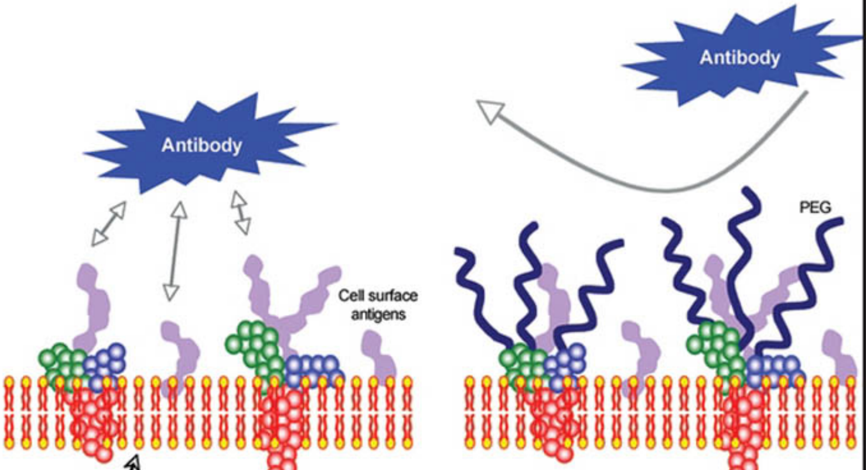
Handbook of Pharmaceutical Biotechnology



Edited by

Shayne Cox Gad

HANDBOOK OF PHARMACEUTICAL BIOTECHNOLOGY

The Wiley Bicentennial–Knowledge for Generations

Each generation has its unique needs and aspirations. When Charles Wiley first opened his small printing shop in lower Manhattan in 1807, it was a generation of boundless potential searching for an identity. And we were there, helping to define a new American literary tradition. Over half a century later, in the midst of the Second Industrial Revolution, it was a generation focused on building the future. Once again, we were there, supplying the critical scientific, technical, and engineering knowledge that helped frame the world. Throughout the 20th Century, and into the new millennium, nations began to reach out beyond their own borders and a new international community was born. Wiley was there, expanding its operations around the world to enable a global exchange of ideas, opinions, and know-how.

For 200 years, Wiley has been an integral part of each generation's journey, enabling the flow of information and understanding necessary to meet their needs and fulfill their aspirations. Today, bold new technologies are changing the way we live and learn. Wiley will be there, providing you the must-have knowledge you need to imagine new worlds, new possibilities, and new opportunities.

Generations come and go, but you can always count on Wiley to provide you the knowledge you need, when and where you need it!

William J. Pesce
President and Chief Executive Officer

Peter Booth Wiley

PREFACE

This *Handbook of Pharmaceutical Biotechnology* represents a unique attempt to overview the full range of approaches to discovering, selecting, and producing potentially new therapeutic moieties resulting from biological process. Such moieties are the backbone of both the pharmaceutical industry and the prime axis for the advancement of medical science.

The volume is unique in that it seeks to cover possible approaches to the biotechnology drug process as broadly as possible while not just doing so in a superficial manner. Thanks to the persistent efforts of Gladys Mok, these 50 chapters cover all major approaches to the problem of identifying, producing, and formulating new biologically derived therapeutics and were written by leading practitioners in each of these areas.

I hope that this second course of our banquet is satisfying and useful to all those working in or entering the field.

Select figures of this title are available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.

1.1

FROM GENE TO PRODUCT: THE ADVANTAGE OF INTEGRATIVE BIOTECHNOLOGY

Frank-Ranier Schmidt
Sanofi-Aventis Deutschland, Frankfurt am Main, Germany

Chapter Contents

1.1.1 Introduction 2
1.1.2 Production of Organisms and Expression Systems 3
1.1.2.1 Industrially Established Recombinant Expression Systems 3
1.1.2.2 Evaluation of Secretory Expression Systems for Pharmaceutical Purposes 5
1.1.2.3 Criteria for the Choice of Recombinant Expression Systems 11
1.1.3 Enhancement of Productivity 13
1.1.3.1 Secretory Recombinant Expression Systems 13
1.1.3.2 Natural Products 13
1.1.3.3 Approaches and Goals for Further Strain Improvement 16
1.1.4 Biosynthetic Structure Modification 19
1.1.4.1 Combinatorial Biosynthesis 19
1.1.4.2 Precursor Directed Biosynthesis 20
1.1.5 Fermentation Optimization and Scale-Up 22
1.1.5.1 Reduced Mixing Quality and Enhanced Stress Exposure 22
1.1.5.2 Process Characterization 26
1.1.5.3 Process Optimization 28
1.1.5.4 Physical Scale-Up Parameters 29
1.1.5.5 Development of Fermentation Models and Strategies 31
1.1.6 Downstream Processing 31
1.1.6.1 Product Recovery and Purification 31
1.1.6.2 Downstream Processing Optimization and Economization 32
1.1.6.3 Downstream Processing Scale-Up 33
1.1.6.4 Downstream Processing of β-Lactam Compounds 34

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

1.1.7 Postsynthetic Structure Modification 34
1.1.7.1 β-Lactam Side Chain Cleavage 35
1.1.8 Quality Issues 37
1.1.8.1 Virus and Endotoxin Removal 38
1.1.9 Conclusion 38
References 38

1.1.1 INTRODUCTION

Biotechnology and biotechnology-based methods are increasing in importance in medical therapies and diagnostics as well as in the discovery, development, and manufacture of pharmaceuticals. Biotechnologically manufactured pharmaceuticals will soon reach a market volume of more than $100 billion USD and, thus, some 20% of the total pharmaceutical market. The key step in their manufacture is the conversion of the genetic information into a product with the desired pharmacological activities by an appropriate selection, design, and cultivation of cells and microorganisms harboring the corresponding biosynthetic pathways and physiological properties.

The intention of this chapter is to give insights into the typical issues and problems encountered in the manufacture of biopharmaceuticals, to mediate general ideas and current strategies on how to proceed in the design and development of biotechnological processes, and to deliver the immediate theoretical backgrounds necessary for comprehension rather than to give detailed experimental instructions like a manual does. In focusing on gene recombinant proteins and peptidic antibiotics, the biotechnologically produced pharmaceuticals with the highest market share, representative aspects will be discussed (1) for process development and optimization approaches to increase product yield and process rentability and to ensure a consistent product quality, (2) for experimental approaches to design and to modify the molecular structure of compounds to meet specific medical needs, (3) for the replacement of chemical procedures by economically and ecologically advantageous biotechnological processes, (4) for critical issues of product purification, and (5) for specific demands in pharmaceutical production to conform to regulatory requirements. Finally, the advantage of an integrative biotechnology is emphasized, which designs the biosynthetic steps of the product in accordance with the requirements of product purification procedures already during early development stages.[1]

For further reviews comprehensively illustrating issues of biotechnological production processes, the reader is referred to further review articles [1–8]. To look up basic subjects of molecular and cellular biology, the reader is referred to textbooks [9, 10].

[1] Parts of this chapter were excerpted and modified from previously published reviews of the author [16, 86, 98, 113, 273] by courtesy of Springer-Verlag, Heidelberg.

1.1.2 PRODUCTION ORGANISMS AND EXPRESSION SYSTEMS

Design and development of all microbial production processes start with the selection of appropriate organisms, strains, and expression systems enabling high yields and high quality of a desired product with defined pharmacological properties.

1.1.2.1 Industrially Established Recombinant Expression Systems

Industrially established expressions systems for production of the marketed compounds are, besides inclusion, body-forming *Escherichia coli* strains, the yeast *Saccharomyces cerevisiae* and mammalian cells like CHO- and BHK-cells (Table 1.1-1). These systems were the genetically and physiologically most advanced and therefore mostly applied when recombinant production processes were starting to be developed in the mid-1980s and are now widely accepted by regulatory bodies. *E. coli* and *S. cerevisiae* can be grown cheaply and rapidly, are amenable to high cell density fermentations with biomasses of up to 130 g/L, possess short generation times, have high capacities to accumulate foreign proteins, are easy to handle, and are established fermentation organisms.

However, because gene recombinant pharmaceuticals continuously gain an increasing importance in medicine and are expected to help curing diseases that are not yet treatable today, new expression systems have to be exploited enabling the production of such pharmaceuticals with innovative properties that simultaneously meet key criteria like consistent product quality and cost effectiveness. Of particular interest in this regard are expression systems enabling the secretion of

TABLE 1.1-1. Industrially Used Recombinant Expression Systems

Product	Company	System
Blood coagulation factors (VII, VIII, IX)	Novo-Nordisk/Bayer/ Centeon Genetics Baxter/ Centeon/Wyeth	BHK-Cells CHO-Cells
Calcitonin	Unigene	*E. coli*/CHO-Cells
DNase (cystic fibrosis)	Roche	CHO-Cells

Recombinant plasminogen-activator	Genentech/Roche/Boehringer	*E. coli*
Stem cell factor	Amgen	CHO-Cells
Tumor necrosis factor	Boehringer	*E. coli*

Note: Overview on the currently worldwide commercialized recombinant pharmaceuticals and the expression systems employed for their production. The substances are not listed strictly alphabetically but are partially grouped according to therapeutic areas. Antibodies, which are mostly manufactured by hybridoma cell line systems, are not considered. Data were extracted from the European patent database Esp@cenet (http://de.espacenet.com) and the IDdb3-database (http://www.iddb3.com). BHK = baby hamster kidney; CHO = chinese hamster ovary. (Taken from Ref. 16 © Springer-Verlag, Heidelberg)

correctly glycosylated and folded proteins into the culture broth. Such secretory systems offer advantages in terms of simple and fast product purification procedures and the avoidance of costly cell rupture, denaturation, and refolding processes (see Section 1.1.4) and thus conform to the requirements of an integrated production process.

Even though animal and plant systems (molecular pharming, [11]) and secretory plant cell culture systems have received a great deal of attention, their commercial feasibility is still under investigation, particularly with respect to their slightly different posttranslational modification modus leading to an altered pharmacological behavior and to allergenic properties [12, 13]. Established in the pharmaceutical

industry as production organisms are, besides the above-mentioned systems, further prokaryotic and yeast species as well as filamentous fungi, which are already employed for the manufacture of natural products (see Section 1.1.2.2).

The suitability of the most prominent secretory systems among these organisms from the viewpoint of an integrative process design for the manufacture of recombinant proteins will be evaluated in the next section by discussing their potential productivity and their physiological properties.

1.1.2.2 Evaluation of Secretory Expression Systems for Pharmaceutical Purposes

Escherichia Coli. As *E. coli* lacks fundamental prerequisites for efficient secretion, the marketed pharmaceuticals (Table 1.1-1) manufactured by *E. coli*-systems are mostly produced as inclusion bodies. Due to the membrane structure, the low chaperone and foldase level and the high periplasmatic protease concentration *E. coli*-secretion systems allow only comparably low product yields, making them suitable only for compounds marketed in small quantities like orphan drugs. Genentech (San Francisco, CA), for instance, has patented a secretory *E. coli*-system for the preparation of human growth hormone [14]. The secretory potential of *E. coli* is indicated by exceptional high product titers in the range of several grams per liter, which were reached in a system developed for secretion of hirudin using the alpha-cyclodextringlykosysl-transferase signal sequence as a leader und secretor mutants deficient in their membrane structure [15]. Titers of human-insulin-like-growth-factor or human-epidermal-growth-factor were reported to be as high as 900 mg/L and 325 mg/L, respectively [references in 16]. Most of the reached and published data, however, refers to processes leading to a periplasmatic product concentration (e.g., 2 g/L of a human antibody fragment, 700 mg/L of a monoclonal antibody) or stays below 100 mg/L, a value that generally is not considered to be in a competitive and economic range. Efforts are thus undertaken to condition *E. coli*-strains to efficient secreters. The main strategies to enhance secretion efficiency [17–19] comprise (1) employment of well-characterized secretion pathways like the alpha-hemolysin system [20] or components of such pathways like efficient signal sequences from efflux proteins [21] or outer membrane proteins [22], for instance, the maltose binding protein [23] or the TolC-protein [24]; (2) variation of the signal peptide; (3) cocloning of and coexpression of chaperones and foldases [25–27]; (4) enhancement of gene expression by employment of strong promotors and efficient transcription termination sequences; (5) generation of protease deficient mutants; (6) generation of cell wall lacking or cell wall deficient mutants [28, 29]; and (7) modulation of the protein primary structure that was found to exert a strong influence on productivity and secretion efficiency by influencing protease resistance, folding efficiency, and the tendency to form inclusion bodies. Details of the strategies for the design and development of secretory *E. coli* strains as well as for the controlled soluble cytoplasmatic expression of recombinant proteins may be taken from general reviews [17, 30–32].

Alternative Prokaryotic Expression Systems. In addition to conditioning *E. coli*-strains to efficient secreters, alternative species, which are considered to inherently possess a superior secretion capacity, are tried to be established as expression

systems. Comparably high product yields of 2 g/L and 1 g/L were reported for production of human calcitonin by *Staphylococcus carnosus* [33] and of proinsulin by *Bacillus subtilis* [34], an organism that is continuously characterized and improved as a cell factory for pharmaceutical proteins [8]. *Bacillus megaterium*, which is thought to be as efficient as *B. subtilis*, is currently developed as a secretory expression system by a Collaborative Research Center (SFB) of the German Research Community (DFG). For *Ralstonia eutropha* (formerly *Alcaligenes eutrophus*), employed at ICI and Monsanto for polyhydroxyalkanoate production at a scale of several 100 m^3 and genomically completely sequenced, 1,2 g/L of secreted organophosphohydrolase, a model enzyme proned to form inclusion bodies in *E. coli*, were reported [35]. *R. eutropha* displays a more efficient carbohydrate metabolism than *E. coli* and is easily amenable to high cell density fermentations with biomass concentration of more than 150 g/L dry weight. This permits a lower specific productivity that in turn reduces the inclinement to form inclusion bodies and thus enables a more efficient secretion. *Rhodococcus*, *Corynebacterium*, *Mycobacterium*, actinomycetes, and streptomycetes [36] are also considered to be potentially suitable for the development of efficient secretion systems. A comparative study with recombinant alpha-amylase demonstrated that final yields as well as enzyme activity were considerably higher when produced by *Streptomyces lividans*, by which it was completely secreted than by *E. coli* in which it was concentrated periplasmatically [37]. The yields reported so far, however, are still below cost-efficient ranges. A system developed by Hoechst/Aventis for insulin production yielded around 100 mg/L, and the yields of correctly folded human CD4-receptor sites are in the range of 200 mg/L. Attached as signal proteins were the prepeptide of the alpha-amylase inhibitor from *S. tendae* (tendamistat) and the signal sequence of a protease inhibitor (LTI) from *S. longisporus*. In the course of these studies, it was found that the choice of the linker and its length strongly influences secretion efficiency. The comparably low yields, however, demonstrate that still a lot of fundamental research is necessary to render streptomyces systems competitive. (Strategies and examples for enhancement of recombinant protein expression in *S. lividans* and the current status of the genetic and physiological development are given in Refs. 38 and 39.) A general focus of research will be the detailed exploration of the twin arginine translocation (TAT) pathway, which has been recently discovered in addition to the conventional prokaryotic secretory (sec) pathways and enables the export of proteins with cofactors in a fully folded conformation [40, 41]. It evidently plays a more important role in *Streptomyces* species [42] but might also be useable in other species.

As the potential and capacity of prokaryotes for prosttranslational modification appear to be quite limited and the knowledge about the pathways is quite scarce (reviews on bacterial protein glycosylation see Refs. 43 and 44), the employability of most of the known prokaryotes usually is restricted to the preparation of proteins that are naturally not glycosylated, such as insulin, hirudins, or somatotropins, or to natively glycosylated proteins that are pharmacologically also active without glycosylation, like various cytokines (tumor necrosis factor, interleukines, interferones). For production of proteins that are pharmacologically active only with an appropriate modification pattern, eukayotic cell systems are more suitable.

Yeasts. Besides possessing complex posttranslational modification pathways, they offer the advantage to be neither pyrogenic nor pathogenic and to secrete more

efficiently. Species established in industrial production procedures are *Saccharomyces cerevisiae*, *Kluyveromyces lactis, Pichia pastoris*, and *Hansenula polymorpha*, which will be dealt with more in detail in this section. Whereas *S. cerevisiae* is the best genetically characterized eukaryotic organism at all and still is the prevalent yeast species in pharmaceutical production processes (Table 1.1-1), *P. pastoris*, first employed by Phillips Petroleum for single-cell-protein production, is currently the most frequently used yeast species for heterologous protein expression in general. Whereas only just a few proteins were expressed by *Pichia* species at the beginning of the last decade [45], the expression of more than 400 proteins have been meanwhile reported now [46, 47]. *P. pastoris* is considered to be superior to any other known yeast species with respect to its secretion efficiency and permits the production of recombinant proteins without intense process development. The highest yields were reported for murine collagen (15 g/L), tetanus toxin fragment C (12 g/L compared with 1 g/L in *S. cerevisiae*), human serum albumin (10 g/L compared with 3 g/L in *K. lactis* and to 90 and 150 mg/L in *S. cerevisiae*), and human interleukin 2 (10 g/L). The highest reported yields for *H. polymorpha* relate to phytase (13,5 g/L) and to hirudin (g/L range) and for *K. lactis* to human serum albumin (3 g/L, see above). Even though *S. cerevisiae* offers a high secretory potential as evidenced by some 9-g/L secreted *Aspergillus niger* glucose oxidase [references in 16], such data document a general inferior secretory capacity, the reasons for which are numerous. For the methylotrophic species *Hansenula* and *Pichia* and the lactose using *K. lactis*, natively strong promoters are available that derive from the methanol and lactose assimilating pathways and their enzymes (e.g., alcohol- and methanol oxidase, lactose permease, galactosidase). As the enzymes of these pathways account for up to 30% of the total protein content, the metabolic efficiency with respect to the secreted protein is significantly higher as documented by Buckholz and Gleeson [48]: Only one or a few gene copies are sufficient in *P. pastoris* to gain the same yields as with 50 gene copies in *S. cerevisiae*. Furthermore, proteins with a molecular mass of above 30 kD are retained in the cytoplasma of *S. cerevisiae*, whereas *H. polymorpha* efficiently secretes proteins with a molecular mass of up to 150 kD, like the glucoamylase of *Aspergillus niger*. [Detailed overviews on the physiological properties of methylotrophic yeasts and *K. lactis* with respect to their use for recombinant protein production is given in Refs. 46, 47, and 49–53]. Further reasons for the differing secretion rates among the species are the specific proteolytic activities and the specific degrees and patterns of glycosylation. Besides having an impact on the protein's final pharmacological activity, glycosylation also exercises an influence on the folding and secretion efficiency. Among the discussed species, *S. cerevisiae* was shown to possess, besides a higher enzymatic activity in the secretion vesicles that leads to a reduced portion of intact secreted proteins [54], also the highest glycosylation capacity leading to a hyperglycosylation of the protein and a reduced secretion rate. Both the degree and the pattern of glycosylation are dependent on the genetic background of the species and strains employed as well as on the sequences of the expressed protein and adjacent regions. By employment of the natively highly glycosylated alpha-mating type factor as a secretion signal, the extent of the glycosylation of the product can be diminished or completely avoided as shown for human interleukin 6 [55]. NovoNordisk reported leader sequence-dependent insulin yields in *S. cerevisiae* [56] and in *S. cerevisiae* and *P. pastoris* [57]: The sequence and therewith the degree of glycosylation of the leader influences the

efficiency of the multistage cleavage and folding processes as well as the insulin glycosylation rate and secretability. Further enhancement of the secretion efficiency can be achieved by (1) mutating secretion enhancer genes [58], (2) suppressing secretion blocking functions, and (3) reducing proteolytic activities in secretion vesicles [54]. So-called supersecreter strains of *S. cerevisiae* have, for instance, been generated by inactivation of the PMR1 (SSC1) function and suppression of the secretion blocking ypt1-1 gene: the yields of non-glycosylated human pro-urokinase [59], of human serum albumin, and of human plasminogen-activator have been augmented to a factor of up to 10 [60]. The traditional approaches pursued for enhancement of gene expression are gene amplification, employment of strong promoters, and enhancement of the transcription and translation rate. A high amplification of the gene copy number [45, 46, 61] usually is achievable with episomal vectors, which however do not reach the mitotic stability of integrative systems like the transposon (e.g., Ty-element) mediated embedment of reiterative, dispers repetitive sequences in *S. cerevisae*. Transcription rates were reported to be enhanced up to 100 times through cotransformation with transcription activators and enhancers, which evidently are limiting factors for overexpression of foreign proteins [62, 63]. Translation efficiency can be enhanced by preventing an accelerated degradation of transcripts and the yeast typical random transcription termination through modulation of the recognition sequences. Prevention of the random transcription termination led to an increase of tetanus toxin fragment C yields in *S. cerevisiae* by a factor 2000–3000 to 1 g/L and 3% of the total soluble protein fraction [64].

Despite their physiologically advantageous properties and natively high expression and secretion capacity, just one industrial application is reported for each of the alternative yeast species: *H. polymorpha* is employed for hepatitis B vaccine production at Rhein-Biotech (Düsseldorf, Germany), *K. lactis* for bovine prochymosin production in a 40-m^3 scale at Gist-Brocades (Delft, Netherlands), and *P. pastoris* for production of recombinant carboxypeptidase B and trypsin at Roche (Basel, Switzerland). For pharmaceutical application, it has to be considerered that the methylotrophic yeasts in contrast to *S. cerevisiae* and *K. lactis* are not used in the production of foodstuffs and therewith have no GRAS (generally regarded as safe) status according to the U.S. Food and Drug Administration (FDA) criteria and have to be grown in expensive explosion-proofed equipments when the above-mentioned native induction systems are used. The discussed properties of the mentioned yeast species are compiled in Table 1.1-2 for comparison. The employ-

TABLE 1.1-2. Typical Sequence of Biotechnological Production Process Steps

Step	Method/Approach
Selection/design/engineering/ development of an appropriate species/strain/ expression system	**Criteria:** pharmacological activity and properties of the compound, productivity, process behavior, suitability for downstream processing steps, spectrum and pharmacological activity of side products to be removed, experimental experience with the respective system, biological and medical safety, acceptance by regulatory bodies

TABLE 1.1-2. *Continued*

Step	Method/Approach
Strain improvement	Mutation/selection, strain recombination (e.g., breeding/protoplast fusion), directed genomic alteration/metabolic engineering/enhancement of gene expression rates
Biosynthetic product structure modification	Amino acid exchange/combinatorial biosynthesis/precursor directed biosynthesis
Fermentation optimization	Empirical optimization of culture conditions (media components, pH, oxygen supply), clarification of the influence of process parameters on growth, productivity and side product formation
Fermentation scale-up	Detailed process characterization for reduction of stress exposure, insurance of homogenized reaction conditions, and identification of suitable scale-up parameters (e.g., with the help of chemometric modeling, computational fluid dynamics)
Downstream processing	
Cell separation and harvest, removal of particulate matters	Centrifugation (decanter, disk-stack separator, (semi)continuous centrifuges), filtration (dead-end, tangential flow filtration)
Cell rupture	High-pressure homogenization, bead mills, sonication, enzymatic treatments
Product capture	Filtration (micro-, ultra-, nano-filtration), precipitation, solvent extraction, ion exchange, size exclusion, affinity chromatography
Product purification/polishing	Hydrophobic interaction/reversed-phase chromatography
Clearance of contaminant agents (e.g., viruses, endotoxins)	Nano-filtration, heat, pH, chemical inactivation, ultraviolet, gamma irradiation
Drying	Heat, freezing, vacuum
Galenic preparation/filling	Addition of galenic excipients, supplements, stabilizers, and adjuvants

Notes: Comprehensive overview illustrating the typical steps of a biotechnological production process. Production starts with the selection of an appropriate species and strain and the engineering of an expression system that enable high product yields and permit easy handling during strain development, fermentation, and downstream processing. Classic measures for improvement of the selected strains and expression systems are mutation and selection runs, breeding, directed genomic alterations, metabolic engineering, and measures aimed at the enhancement of expression rates of genes involved in product biosynthesis. Cultivation of the cells occurs under suitable conditions permitting strong growth, high product yield, and high product quality and facilitating product recovery and purification during downstream processing, which usually starts with separation of the product from the biomass and the culture broth by centrifugation or filtration. Before the separation of intracellular occurring products, cells have to be ruptured by high-pressure homogenization (e.g., in a homogenizer, a Dyno mill, or a French press). For high product purity, high recovery rates and simultaneous maintenance of the pharmacological activity, product purification and polishing usually occurs by solvent and solid-phase extraction. The choice of suitable resins and solvents and their combinations is highly dependent on the chemical and physical properties of the product and the side metabolites to be removed.

The final step consists of product concentration and drying, e.g., by heat, freezing, and/or vacuum before the galenic preparation. The discrimination between product capture and polishing is somewhat arbitrary as is the assignment of the respective methods. Depending on the product and the individual product properties, the transitions between the steps are gliding and the methods can change accordingly.

ability of yeasts in some cases however might reach a limit, particularly when the pharmacological activity of the product is impaired by the glycosylation pattern. In *K. lactis*, for instance, which usually does not hyperglycosylate, an exceptional high glycosylation of human interleukin 1β has been observed, reducing the biological activity to 5% [65, 66]. In such cases, a postsynthetic chemical modification has to be considered or the employment of higher developed organisms.

Filamentous Fungi. Filamentous fungi are higher organized than yeasts and consequently have a more complex posttranslational modification apparatus more similar to mammals. Some proteins like t-PA in *Aspergillus nidulans* are produced with the natural human glycosylation pattern. For recombinant protein production, species are prefered, which are broadly employed in industry for production of enzymes, acids and antibiotics and thus possess GRAS-status: *A. nidulans*, *A. niger*, *A. sydowii*, *A. awamori*, various *Fusarium* and *Trichoderma* species, *Penicillium chrysogenum*, and *Acremonium chrysogenum*. Their productivity and secretion potential, which is in the range of 30–40 g/L for homologous enzymes like cellulases and amylases, is considered to be superior to any other system, but unfortunately could not be converted into corresponding yields of recombinant products, even when these were fused to such homologous enzymes. The highest yields are still obtained with heterologous fungal enzymes: 4-g/L *Fusarium* protease in *A. chrysogenum* and 4.6-g/L *A. niger* glucoamylase in *A. awamori*. The highest yield of a mammalian protein was reported for human interleukin 6 in *A. sojae* in a range of 300 mg/L [references in 16]. The yields of most human proteins like t-PA and various interferons, however, were reported to be below 1 mg/L [67–71]. Possible reasons for these incompetitive yields are restrictions in posttranslational metabolic steps like intracellular transport, folding, and processing. Even though filamentous fungi are industrially used now for decades, they are not adequately characterized on the physiological and genetic level. Little is known about details of the modification and secretion metabolism, and efficient gene transformation is hampered by degradation of foreign DNA, low transformation rate, and therefore, low copy numbers of the transferred genes and random genomic integration. Expression rates are restricted by a high RNA turnover, incorrect processing of the foreign messenger, and incomplete folding and secretion, which are, as in yeasts, both influenced by the glycosylation pattern. Proteins not completely or incorrectly glycosylated and excreted are rapidly degraded as shown for human interleukin 6 [71]. Currently, filamentous fungi cannot be regarded as a serious alternative for the production of pharmaceuticals. To fully exploit the potential of filamentous fungi, their physiology, particularly the glycosylation metabolism, thus has to be investigated and clarified in more detail.

Insect and Mammalian Cell Cultures. Animal cell cultures are the systems with highest similarity to human cells with respect to the pattern and capacity of posttranslational modifications. However, their cultivation is more complicated and costly and usually yields lower product titers. Among the known systems, insect cells transformed by baculovirus vectors have reached a comparable popularity as *Pichia* among yeasts because they are considered to be more stress resistant, easier to handle, and more productive compared with mammalian systems and are thus frequently employed for high-throughput protein expression. The highest reported

yields refer to human collagenase IV in *Trichoplusia* (300 mg/L). Yields reported for non-insect cultures were 80 mg/L for human apolipoprotein A1 in chinese hamster ovary (CHO)-cells and 1 mg/L for human laminin in human embryonal kidney cells [references in 16]. For commercial application scale-up, related questions have to be clarified, particularly concerning oxygen supply [72] and carbon dioxide accumulation [73], stability of the cell line, and the bioreactor type to be employed [74]. Further deficiencies of insect cells are observed in (1) an inefficient processing and an impairment of the folding and secretion capacity due to the baculovirus infection [75]; (2) the high, in part baculovirus encoded, protease activity and the resulting necessity to routinely employ protease inhibitors in the culture media or to develop protease deficient vectors [73]; (3) an insufficient expression strength; and (4) deviations of the posttranslational modification pattern, which could act immunogenic. For optimization, the construction of new innovative vectors and the coexpression of chaperones, foldases, and folding factors such as canexin [76] have been suggested as has been the broader development and application of alternative systems like *Drosophila* [75]. Preferably applied in pharmaceutical production processes are mammalian systems like CHO- and baby hamster kidney (BHK)-cells (Table 1.1-1). These systems are generally considered to be genetically more stable and easier to transform and to handle in scale-up processes, grow faster in adherent and submerged cultures, and are more similar to human cells and more consistent in their complete spectrum of modification [77], which minimizes the risk of the formation of structurally altered compounds with immunogenic properties. In some cases, mammalian systems can be the only choice for the preparation of correctly modified proteins. Studies of Tate et al. [78] comparing the expression of a rat serotonin transporter in various expression systems demonstrate that biologically active transporter was only synthesized in mammalian cells, whereas it was partially degraded in *E. coli*, not correctly folded in *Pichia* and not correctly glycosylated in insect cells. CHO- and BHK-cells further have the advantage to be recognized as safe regarding infectious and pathogenic agents and therefore to have a higher acceptance by regulatory bodies, which accelerates or at least does not delay approval procedures. [Issues related to the physiology and the technical handling of mammalian cell cultures in the manufacture of human therapeutics are discussed in detail in Refs. 74 and 79–81].

1.1.2.3 Criteria for the Choice of Recombinant Expression Systems

In summary, the criteria for the choice of an expression system in pharmaceutical production [82] are the existing expertise, the available physiological and genetic know-how and tools, the patent situation, and to avoid delays of product launch and commercialization, regulatory aspects like the acceptance by the approving authorities.

The overall decision criteria, however, is the pharmacological activity profile of the yielded protein in context with the posttranslational modification pattern followed by rentability.

For production of non-glycosylated proteins and proteins that are natively glycosylated but pharmacologically active also without glycosylation, prokaryotes, which usually lack metabolic pathways for glycosylation, theoretically are the most

suitable organisms, offering two alternatives: Either *E. coli*-strains are conditioned to efficient secreters, or efficient native secreters like *Bacillus*-species are accordingly developed. (The implications of the glycosylation pattern for the choice of expression systems and the physiology of glycosylation is reviewed and discussed in Ref. 83.) To fully exploit the secretion capacity of fungal species, a deeper understanding of their posttranslational modification physiology will be necessary to steer the degree and pattern of glycosylation, which influences both folding and secretion efficiency. Insect and mammalian cells display posttranslational modification patterns more similar or identical to humans, but in view of the entailed expenditures, their employment can only be justified if their modification machinery is required to ensure a desired pharmacological activity.

E. coli, *P. pastoris*, and Baculoviru*s*-based systems are currently preferred in fundamental research for structural and functional analysis of proteins and are employed as high-throughput-expression systems but will certainly find their ways into production processes in the near future. None of the systems, however, can be considered to be generally superior to any other. For each product, the most suitable expression system has to be identified and optimized individually both on the genetic and on the fermentative level by taking into account the properties of the product, the organism, and the expression cassettes, which suggests to always have a set of accordingly developed expression systems available. Some key properties of the established expression systems are compiled in Table 1.1-3. A review on properties and prospects of further alternative systems is given in Ref. 84.

Once an expression system has been selected, the respective strains are continuously submitted to improvement programs to render fermentation processes more efficient by increasing strain productivity and by modifying physiological properties and process behavior to enhance process economy. This does not only apply to the fermentation process, but also to parts of downstream processing, thus requiring an integrated strain selection and process design. Strategies to improve productivity of secretory recombinant systems and of strains employed for the manufacture of natural products will be outlined in the next section.

TABLE 1.1-3. Features and Characteristics of Expression Systems

Property	Bacteria	Yeast	Insect and Mammalian Cell Cultures
Growth	Fast	Fast	Slow
Nutrient demand	Minimal	Minimal	Complex
Costs of media	Low	Low	High
Possible product yield	High	High	Low
Secretory capacity	Limtited	High	Medium
Glycosylation capacity	Limited	High	High
Modification capacity	Limited	High	High
Risk of retroviral Contamination	Low	Low	High
Risk of pyrogens	High	—	—
Scalability	Good	Good	Low
Process robustness	Good	Good	Low

1.1.3 ENHANCEMENT OF PRODUCTIVITY

1.1.3.1 Secretory Recombinant Expression Systems

In terms of downstream processing efficiency, secretory expression systems indeed offer potential advantages for production of recombinant proteins compared with inclusion body-forming cytosolic systems, but most of the potentially available secretory systems are not yet fully competitive for high-volume therapeutics like insulin and therefore still require intensive improvement efforts.

Current strategies to improve productivity and secretion efficiency comprise (1) enhancement of gene expression rates, (2) optimization of secretion signal sequences, (3) coexpression of chaperones and foldases, (4) creation of protease deficient mutants to avoid premature product degradation, and (5) subsequent breeding and mutagenesis.

1.1.3.2 Natural Products

Completely different is the situation faced in the production of the so-called natural products, which are mostly secondary metabolites and therewith the endproducts of complex biosynthetic pathways of filamentous bacteria and fungi and thus require different approaches. With few exceptions like the antidiabetic drug acarbose (Glucobay) [5] or the chosterol-lowering drug lovastatin (Mevicor) [85], such fermented pharmaceuticals of natural origin currently belong for the most part to the class of antibiotics [86].

Enhancement of the productivity is achieved at first by rounds of random mutation and selection and, if possible, by breeding, and/or by DNA injection or fusion techniques like protoplasting and at further stages, after a comprehensive characterization of the usually complex biosynthetic pathways, directed genomic alterations and metabolic engineering.

These approaches, developments, and states in industrial strain improvement and pathway characterization will be illustrated for some of the best characterized organisms, namely the two fungal species mainly employed in industrial β-lactam antibiotic production, the penicillin producing *Peni-cillium chrysogenum*, and the cephalosporin C producer *Acremonium chrysogenum*.

Characterization of Biosynthetic Pathways. The productivity of *Penicillium chrysogenum* could have been augmented impressively during the last decades: Penicillin titers have been increased by a factor of 50,000 from a very few milligrams/Liter in the 1940s to more than several 10 g/L by now and also some several 10 g/L cephalosporin are currently gained.

This development, however, has come to a halt during the last couple of years. As these titers have been reached through conventional mutation and selection [87–90] and no further significant increase in productivity could be noted, the tools of genetic engineering were more and more included into the improvement programs [91]. To gain a profound basis for directed genomic alterations, studies were conducted at various corporations and universities to elucidate the mechanisms and genes involved in β-lactam biosynthesis to characterize the respective biosynthetic pathways. As the results and achievements of these studies have already been

reviewed extensively and in detail elsewhere [92–97], the current knowledge will only shortly be summarized.

Cephalosporin C Synthesis in Acremonium Chrysogenum. Biosynthesis (Figure 1.1-1) starts with the polymerization of L-α-aminoadipic acid, L-cysteine, and L-valine to the linear tripeptide L-α-aminoadipyl-L-cysteinyl-D-valine (ACV-peptide). This reaction is catalyzed by the ACV-synthase (MW about 420 kD) through the following steps: (1) the ATP-dependent activation of these amino acids to bind them as thiolesters, (2) the epimerization of L-valine, and finally (3) the condensation by a thiotemplate mechanism [99].

Cyclization of the ACV-peptide to the bicyclic isopenicillin N (IPN) occurs under oxygen-, Fe^{2+}-, ascorbate-, and α-ketoglutarate-dependent action of the IPN-synthase (IPNS), which has an MW of about 38 kD. Inhibitory to IPNS activity are cobalt ions and glutathione.

Further pathway reactions are as follows:

- IPN-epimerization to penicillin N (IPN-epimerase).
- Penicillin N conversion to deacetoxycephalosporin C (DAOC) by expansion of the five-membered thiazolidine ring to a 6 C-dihydrothiazine-ring (DAOC-expandase).
- Formation of deactylcephalosporin C (DAC) by dehydroxylation and oxidation of the methylgroup in C3-position (DAC-hydroxylase).
- The acylation of DAC to cephalosporin C (DAC acetyltransferase).

DAOC-expandase and DAC-hydroxylase activities in *A. chrysogenum* are exerted by the same enzyme (MW 41 kD), which like the IPNS belongs to the group of α-ketoglutarate-dependent dioxygenases.

The first two enzymes, ACV- and IPN-synthase, are encoded by the *pcbAB*- and the *pcbC* gene, respectively. Both genes are linked to each other on chromosome VI by a 1.2-kb intergenic region carrying the putative promotor sequences from which they are divergently transcribed. The *pcbC*-promotor seems to be about five times stronger than the one of the *pcbAB*-gene [100]. The *cefEF*-gene and the *cefG*-gene encoding for the bifunctional expandase/hydroxylase and the DAC-acetyltransferase, respectively, are located adjacent to each other on chromosome II. Again the genes are separated by an intergenic region of 938 bp, which is supposed to harbor the promotors from which they are transcribed in opposite directions. The *cefG*-gene has been proven to contain two introns [101]. Due to an extreme *in vitro* lability, no information is yet available on the epimerase converting IPN to penicillin N as well as its putative *cefD* gene. Until recently, the structure of the *cefD* gene could have not been elucidated. Meanwhile, data could have been obtained indicating the existence of two reading frames (*cefD1* and *cefD2*) containing all characteristic motifs of mammalian acyl-CoA ligases and α-methyl-acyl-CoA racemases [93].

Regulatory studies demonstrated that the early functions are expressed simultaneously, whereas the later pathway genes *cefD* and *cefEF* seem to be induced sequentially.

In contrast, the penicillin biosynthesis genes in *P. chrysogenum* are considered to be expressed completely concomitantly.

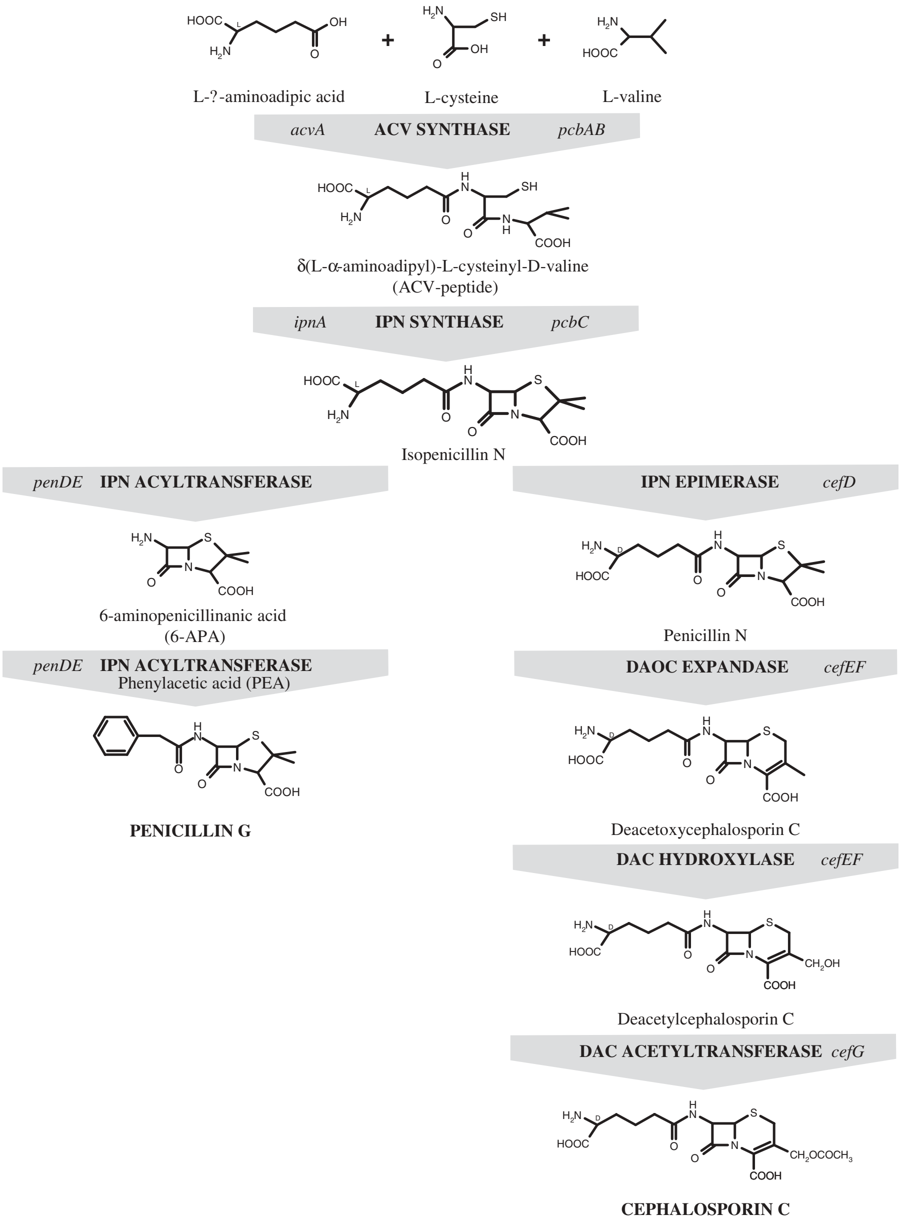

Figure 1.1-1. Biosynthetic pathways of penicillin G and cephalosporin C. In contrast to recombinant proteins, the structure and production of which can easily be modified by alterations of the encoding DNA sequence and the use of stronger promoters, respectively, structure modification and enhancement of expression rates of natural products by directed genomic alteration and metabolic engineering require a detailed characterization of the biosynthetic pathways as it has been performed for penicillin and cephalosporin biosynthesis in the filamentous fungi *Penicillium chrysogenum* (left) and *Cephalosporium acremonium* (right). Enzymes (bold) and genes are underlined by gray arrows. The first two reaction steps are common to both pathways. Cleavage of isopenicillin N to 6-APA and the subsequent acylation to penicllin G in *P. chrysogenum* and the expandase/hydroxylase activity in *A. chrsyogenum* are exerted by bifunctional enzymes. For details, see text. (Graph taken from Ref. 98, © Springer-Verlag, Heidelberg.)

Penicillin Formation by Penicillium Chrysogenum. The first reactions of the penicillin biosynthetic pathway are identical to the ones in *A. chrysogenum* (Figure 1.1-1). IPN, however, is not epimerized to penicillin N; instead it is converted to 6-aminopenicillanic acid (6-APA) by removal of the L-α-aminoadipic acid side chain, which is substituted by a hydrophobic acyl group. Both steps are catalyzed by the same enzyme, the acyl coenzyme A: IPN acyltransferase (IAT). The enzymatic activity of IAT is believed to be the result of the processing of a 40-kD monomeric precursor into a dimeric form consisting of two subunits with MWs of 11 and 29 kD. Due to the broad substrate specifity of IAT, various penicillin derivatives are synthesized naturally by attachment of different acyl-CoA derivatives to the 6-APA-core. For industrial purposes, to facilitate extraction by organic solvents, synthesis usually is directed to the less hydrophilic penicillin V or penicillin G. This is by addition of phenoxyacetic acid or phenylacetic acid, respectively, as precursors to the culture broth.

The IAT encoding *penDE*-gene (also named *aatA*) is located on chromosome I and organized as a cluster together with the ACV-synthase and IPN-synthase encoding genes *pcbAB* (also named *acvA* in *Penicillium*) and *pcbC* (*ipnA*).

The enzymes involved in penicillin biosynthesis are distributed at different sites of the cell: ACV-activity was found to be bound to vacuole membranes, IPN-synthase occurs dissolved in the cytoplasm and IAT-activity is microbody associated.

1.1.3.3 Approaches and Goals for Further Strain Improvement

Analysis and Comparison of Strains. To get hints for more rational strain improvement approaches, (1) highly mutated production strains were genetically and physiologically compared with their less-productive ances-tors, (2) concentrations of pathway intermediates were determined to identify potential pathway bottlenecks, and (3) regulatory mechanisms were investigated.

In the course of such studies, high-performance strains of *P. chrysogenum* turned out to possess amplified copies of single genes like the *pcbC* gene or even copies of the whole cluster as well as increased steady-state transcript levels of pathway genes [102–104]. In some strains, the amplifications were shown to be organized in tandem repeats, which presumably were generated by a hot-spot TTTACA hexanukleotide [105]. Comparison of promotor strengths of these genes from high and low productive strains did not reveal any differences. This indicates the involvement of additional unknown trans-acting factors [106], as the amounts of increased mRNA did not correlate with the degree of gene amplification. Also a high specific activity of IPN synthase was reported in a more evolved *Penicillium* strain, which was independent from transcript amounts and probably due to a higher enzyme stability [102, 107].

In *A. chrysogenum*, no amplification of the relevant genes could be detected. Nevertheless, transcript amounts in production strains are significantly increased [108].

Also chromosome rearrangements could be detected in high titer strains [109–111], but their causative influence on productivity remains unclarified for the moment.

Directed Genomic Alterations. *Enhancement of Gene Expression.* Con-sidering these findings, the experiments conducted so far to improve productivity mainly concentrated on enhancing the pathway gene dosages and on enhancing promotor strengths to remove presumed pathway bottlenecks. For instance, the *cefEF*-activity was generally believed to constitute a potential rate-limiting step in view of the high accumulation of penicillin N in various strains of *A. chrysogenum* and accordingly amplified.

Such approaches resulted in partially significant increases of productivity in low and medium titer strains: Improvements of the final yields by 50% have been reported [96].

However, all improvements achieved so far with high-performance production strains remained with a 5% maximum in the range of normal statistical deviations.

Also more exotic approaches like the (presumed) improvement of the intracellular oxygen supply through cloning and expressing of a bacterial hemoglobin gene from *Vitreoscilla* [112] failed to increase productivity in high titer strains.

The reasons for these failures are manifold:

1. As both direction and site of integration of the imported DNA cannot be controlled sufficiently and transformation efficiency is still quite low, the probability of finding new, higher producing mutants even in a large-scale screening is rare.
2. Most of the data available are from studies performed at academic institutions with original strains. Even when sharing the same ancestral strain, the high-performance strains employed in industries have an individual genealogy and mutation-selection history, so that their physiological behavior and properties differ drastically. Data and knowledge obtained with a particular strain thus cannot always be generalized and transfered to other strains. Even among industrial strains, significant differences have been revealed. For instance, the expression of the *cefG*-gene and the acetyl transferase activity was reported to constitute a possible rate-limiting step in Panlabs-strains [113]. Studies conducted on other industrial strains, however, could not confirm this observation.
3. The genetic instability and drift rises with the degree of genomic alterations, particularly during long-term vegetative propagation with numerous generation cycles in industrial large-scale fermentations.
4. The complex interdependence with other metabolic areas is not yet completely investigated. Consequently, after removal of an obvious β-lactam pathway bottleneck, unknown reaction steps of the linked and preceding pathways might become flux limiting. To overcome such flux limitations, one of the most exciting recent discoveries in molecular biology, namely RNA interference (RNAi), might play a major role in the future.

The Possible Impact of RNAi in Strain Improvement. The mechanisms of p osttranscriptional gene silencing, generally summed up as RNAi [114] offer potential approaches for the specific shut down of any gene of interest: Native genes can be silenced by triggering the RNAi cascade through introduction of homologous genetic sequences. As a result of these possibilities, RNAi has already

revolutionized fundamental research in molecular biology, particularly in functional genomics, and will substantially contribute to novel therapeutic approaches in medicine [115, 116]. For fungi, which evidently were among the first organisms in which RNAi and associated phenomena were observed [117–122], this RNAi triggered cosuppression phenomenon has been termed "quelling" and bears an enormous potential with respect to the study of biosynthetic pathways and the improvement of metabolic productivity.

On the one hand, the implication of RNAi may supply an explanation for observations made in the course of strain improvement programs of *Penicillium chrysogenum* and *Acremonium chrysogenum*, according to which antibiotic productivity can decrease drastically upon amplification of genes involved in antiobiotic biosynthesis.

The characterization and inactivation of these cosuppression mechanisms thus might help to overcome such limitations as does an application of fungal RNAi tools for silencing of pathway blocking or metabolic flux limiting genes, e.g., by the use of a novel vector system consisting of dsRNA viruses [114].

To fully realize the potential for further enhancement of productivity, which is generally assumed to be in the range of some 300% and to fully exploit the potential of RNAi, current and future studies thus aim at filling the actual gaps of knowledge and will be focused on

- The exploration of regulatory mechanisms and circuits on the transcriptional, translational, and posttranslational level.
- The determination of the specific intermediate turnover rates resulting from specific enzyme activities, enzyme titers, and enzyme stabilities.
- The detailed investigation of linked and preceding pathways.
- The investigation of product secretion mechanisms.

However, as no great leaps in productivity are currently reached, strains emerging from the development programs are also selected for beneficial alterations of genetic, physiological, and morphological properties that contribute to an enhanced process economy.

Improvement of Process Behaviour. Among the desired alterations are:

- A decrease of side products, which (1) consume metabolic energy at the expense of the desired main product, (2) hamper the final product purification, or (3) even can be inhibitory to the production organism. For instance, a significant reduction of DCPC concentrations has been reached through knocking out esterases that hydrolyze cephalosporin C to DCPC during fermentation. Esterase inactivation was by conventional mutagenesis as well as through gene-disruption and by introduction of anti-sense genes.
- Increase of the tolerance toward toxic side products and fed precursors like phenyl- or phenoxyacetic acid (see above).
- Further reduction of feedback inhibition by endproducts and metabolites (see below).
- Further reduction of catabolite repression (see below).

- Enhancement of genetic stability.
- Enhancement of viability, stress resistance, and life span.
- Accelerated product formation and enhancement of time-specific productivity to shorten fermentation time.
- Enhancement of the strain-specific productivity to reduce the amount of biomass to be processed and disposed.
- Increase of product secretion rate.
- Improvement of the fermentation behavior like (1) higher efficiency of substrate/precursor consumption, (2) diminished oxygen demand, and (3) diminished shear sensitivity.
- Improvement of filterability.

The in-depth characterization of physiological properties and biosynthetic pathways not only aims at improving process behavior and process economy, but also it relates to modifications of the inherent biosynthetic pathways (pathway engineering) to create innovative, novel products with improved properties and enhanced therapeutic values, e.g., to overcome the antibiotic resistance problem, a major global health-care problem of today [86].

1.1.4 BIOSYNTHETIC STRUCTURE MODIFICATION

Although the metabolic engineering of beta-lactams by combining β-lactam encoding genes from various sources [95, 123] is still in an explorative state, the study of polyketide pathways and the creation of polyketide antibiotic derivatives is more advanced.

1.1.4.1 Combinatorial Biosynthesis

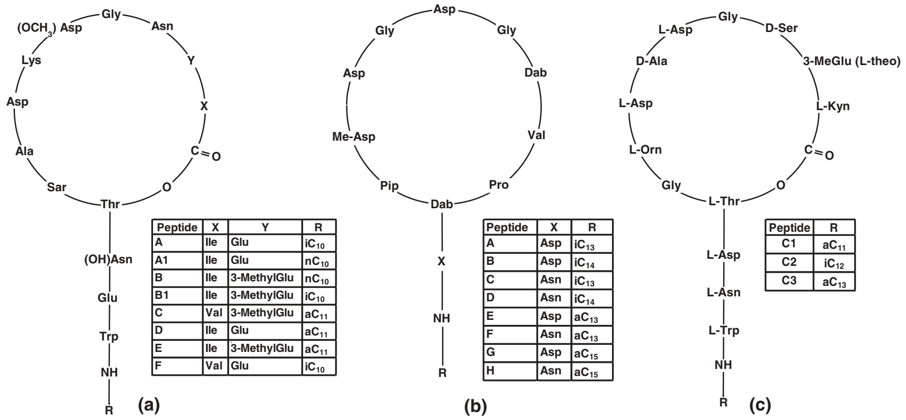
Compounds emerging from the polyketide pathways are the classic subject of metabolic engineering [124] and for creation of novel structures. To create novel antibiotics, the natural biodiversity of polyketides is trying to be enhanced artificially by modifying and newly combining the biosynthetic pathway steps and enzymes involved [125, 126]. Polyketide synthases [127, 128] are multienzyme systems, which due to their modular structure and the occurrence of their encoding genes as clusters, are considered to be most amenable for directed alterations, genetic intervention, and heterologous expression in foreign hosts with different metabolic pathways. Concepts and strategies that are currently being pursued for creating novel and un-natural polyketides [129–132] comprise (1) creating block mutants at various biosynthetic levels to accumulate intermediate metabolites; (2) elimination of unwanted groups; (3) modification of polyketide synthases to further broaden substrate range, eventually combined with a precursor-directed biosynthesis (see below); (4) formation of new structures by deleting or introducing additional modules; (5) modification, addition, or elimination of postsynthetic modification steps like glycosylation, lactonization, and amidation; (6) the cloning and combination of various polyketide synthase genes in heterologous hosts to construct hybrid pathways and antibiotics [130]; and (7) linking and combining routes of polyketides

with pathways of nonribosomal peptide synthesis to create hybrid peptide–polyketide compounds [131–135]. As the microbial nonribosomal peptide synthases share many structural and catalytic properties [136] with polyketide synthases like their organization into catalytic modules and domains [137], they are also envisaged as ideal subjects for metabolic engineering by creating large sets of modules and subsequently combining them artificially [95, 138, 139]. The rapidly growing body of patents makes evident that an increasing number of companies are working on the field of combinatorial biosynthesis. However, it also becomes evident that, despite their promising prospects, these strategies of combinatorial biosynthesis are still in an initial state and need further intense research to elucidate the required genetic and physiological details.

This is just in contrast to another approach of modifying the molecular structure of peptidic compounds on the biosynthetic level, namely the directed biosynthesis of the desired compound structures by feeding of appropriate biosynthetic precursors or stimulating agents during fermentation, as it is routinely performed for production of penicillin V und G by the addition of phenoxyacetic acid or phenylacetic acid, respectively, as precursors to facilitate penicillin extraction from the culture broth.

1.1.4.2 Precursor Directed Biosynthesis

Microbial peptidic compounds can be modified not only in their peptide structure by direct incorporation of amino acids supplemented during fermentation but also, if present, in their fatty acid moiety [140]. The possibilities of precursor-directed derivatization of cyclic peptides cores and fatty acid moieties by amino acids will be illustrated for three compound complexes (Figure 1.1-2) with unique modes of action and outstanding spectra of activity against multidrug resistant germs, which were developed by Aventis, Eli Lilly, and Cubist Pharmaceuticals. The complex A1437 of Aventis is synthesized by *Actinoplanes friulensis* [141], which originally produced a mixture of altogether eight lipopeptides (A–H), classified according to the exocyclic amino acid position and the type of their fatty acid chains [142] (Figure 1.1-2). Through addition of L-valine and asparagines, the biosynthesis could be directed toward the production of the desired D-peptide [143], which exhibited superior pharmacological properties in preclinical trials and is characterized by an exocyclic asparagine and an iso-C14 fatty acid moiety (Figure 1.1-2). The A54145 complex from Eli Lilly [144] exhibits the noteworthy characteristic, that a built-up resistance was immediately lost in the absence of this compound [145]. It consists of eight lipopeptides produced by *Streptomyces fradiae* containing four similar peptide nuclei in combination with three different fatty acid acyl side chains. The nuclei differ in their valine/isoleucine and glutamate/3-methylglutamate substitutions at one or both of two locations of the peptide ring. The composition of the peptide nucleus as well as the percentage of branched-chain fatty acid acyl substituents could be directed by supplementation of either valine or isoleucine [144] (Figure 1.1-2). Likewise, the complex A21978 from *Streptomyces roseosporus*, also developed at Eli Lilly, can be influenced in its composition by modification of the fatty acid chain. Precursing with valine results in an enhanced formation of the compound C2, whereas the compound C1 was preferably built upon feeding of isoleucine [146] (Figure 1.1-2). Compound C1 was inlicensed as



Peptide	X	Y	R
A	Ile	Glu	iC_{10}
A1	Ile	Glu	nC_{10}
B	Ile	3-MethylGlu	nC_{10}
B1	Ile	3-MethylGlu	iC_{10}
C	Val	3-MethylGlu	aC_{11}
D	Ile	Glu	aC_{11}
E	Ile	3-MethylGlu	aC_{11}
F	Val	Glu	iC_{10}

Peptide	X	R
A	Asp	iC_{13}
B	Asp	iC_{14}
C	Asn	iC_{13}
D	Asn	iC_{14}
E	Asp	aC_{13}
F	Asn	aC_{13}
G	Asp	aC_{15}
H	Asn	aC_{15}

Peptide	R
C1	aC_{11}
C2	iC_{12}
C3	aC_{13}

Figure 1.1-2. Structure modification of peptide antibiotics by precursor directed biosynthesis. Biosynthetic structure modification can be performed by metabolic engineering requiring an in-deph pathway characterization or by feeding of appropriate precursor compounds incorporated into the product. Examples are the lipopeptide complexes A 54145 from Eli Lilly (a), A 1437 from Aventis (b), and A 21978 developed by Eli Lilly and Cubist Pharmaceuticals (c) synthesized by *Streptomyces fradiae, Actinoplanes friulensis*, and *S. roseosporus*, respectively. The composition of both the peptide cores as well as the fatty acid moieties can be modulated *in vivo* by supplementation of amino acids like valine, leucine, isoleucine, and asparagine. The addition of valine leads to the preferable formation of peptides A 54145 C and F. The biosynthetic pathways of *A. friulensis* could be directed toward a more specific production of the desired peptide A 1437 D by feeding of valine and asparagines, whereas the preferred compound A 21978 C1 (daptomycin) could be stimulated by the addition of isoleucine. For the further details and references, see text. (Graph taken from Ref. 84, © Springer-Verlag, Heidelberg.)

daptomycin by Cubist Pharmaceuticals for clinical development. However, due to rhabdomyolytic activities and a slight haemolytic potential [138, 147, 148], it has been approved by the U.S. Food and Drug Administration in 2003 as Cubicin® salve for topical use only. Despite such disadvantageous properties, peptides in general, including those that are from nonmicrobial sources and ribosomally synthesized, are currently considered to be among the most promising compound classes for development of novel antibacterials [86, 149, 150].

However, it has to be taken into account that amino acid and precursor incorporation as well as regulation mechanisms of biosynthetic pathways also depend on growth phases, on environmental influences, and thus on the conduction of the fermentation process during which the cells are propagated.

A prerequisite for a successful fermentation are controlled and homogenous environmental conditions for the cellular reactions. However, the ensurance of controlled reaction conditions, particularly in large production scales, has been turned out to be one of the most critical issues of industrial biotechnology, as will be illustrated in the next section. For a detailed discussion of problems specifically related to the fermentation of β-lactam antibiotics, the reader is referred to the review by Schmidt [98].

1.1.5 FERMENTATION OPTIMIZATION AND SCALE-UP

The scale-up of fermentation processes as a central problem in biotechnology was first recognized and described during industrial penicillin production at the beginning of the 1940s and has been studied in more detail in *E. coli* and recombinant protein production.

1.1.5.1 Reduced Mixing Quality and Enhanced Stress Exposure

Fermentation scale-up is aimed at the manufacture of larger product quantities, if at all possible, with a simultaneous increase or at least consistency of specific yields and product quality. The changed geometric and physical conditions in larger scales, however, has lead to a less favorable mixing behavior and to impaired physiological reaction conditions, which in turn may lead to a decreased process constance and reproducibility, to reduced specific yields, to an increase of unwanted side products, and thus ultimately, to a diminished batch-to-batch consistency and product quality, which are all key issues in industrial production processes.

The problem of reduced mixing quality in larger scales is aggravated with increasing vessel sizes: The opposite substrate and oxygen gradients along the vessel height that are formed as a result of the conventional fermenter design, according to which substrate feed usually occurs from the top and aeration from the bottom, are more pronounced in larger reactors due to (1) longer distances to be covered leading to larger substrate and oxygen depletion zones, (2) larger volumes of culture broth to be stirred and therewith longer mixing times, and (3) stronger hydraulic pressure gradients influencing the oxygen transfer rate (OTR; Equations 14 and 15, Table 1.1-4) [151–155]. Cells at the fermenter top are exposed to excess glucose concentrations and simultaneously suffer from oxygen limitations, whereas those at the bottom are exposed to glucose starvation. Excess glucose concentrations (threshold value for *E. coli* at 30 mg/L) result in acetate overproduction (overflow-metabolism), and a simultaneous oxygen limitation further induces the formation of ethanol, hydrogen, formiate, lactate, and succinate (mixed acid fermentation: Refs. 154, 156, and 157). The produced acids can become reassimilated in oxygen-rich zones but in any case first lead to a temporary acidification of the microenvironment and later eventually of larger regions. Combined with a decreased transportation and elimination of carbon dioxide, detrimental metabolites, and surplus heat generated by agitation and metabolic processes, resulting in zonal overheating, the lower mixing rates in large scales thus lead to the formation of zones with enhanced stress conditions. The subsequent activation of stress genes (a survey on bacterial stress proteins is given in Ref. 158) only partially protects the cell against detrimental stress effects. For instance, despite activation of heat stress genes like *E. coli* dnaK and clpB, reducing misfolding and aggregation of heat-sensitive proteins [159], metabolic changes and damages such as translocation of proteins and membranes have been observed upon heat exposure [160]. The evidently unavoidable detrimental effects of the repeated and cyclic passing of different stress zones and the subsequent continuous activation and shut down of the corresponding stress genes are believed to lead to a completely altered physiology [155, 161] with metabolic shifts, which ultimately reduce growth and productivity and increase byproduct formation.

TABLE 1.1-4. Fermentation parameters, coefficients and terms, implicated in mixing, aeration, oxygen, and heat transfer, suitable as scale up variables to be kept constant alone or combined with each other or other process relevant variables, preferably but not necessarily, as dimensionless groups as described and discussed e.g., by Hubbard [228] and Wang and Cooney [230]. For instance, the k_La—value as the most frequently applied physical scale up variable has been combined with [1] the vessel backpressure *p* by maintaining the product of $k_La \times p$ constant through variation of pressure, agitation, and aeration for scale up of *Bacillus thuringiensis* fermentations (Flores et al. [232]) or [2] the aeration rate *vvm* under variation of power input, working volume and aeration according to the Wang-Cooney-equation [217]. For details and further explanations see text (taken from Ref 273 © Springer-Verlag, Heidelberg).

Parameter / coefficient	Mathematical characterization	Symbol explanation
Power input (P); volumetric power input (P/V)	(1) $P = 2\pi n M = N_{Po} \rho n^3 d_I^5$ [$kg\,m^2 s^{-2} = W$]	P = power input; n = stirrer speed; M = momentum; N_{Po} = dimensionless power number (impeller specific);

Heat transfer coefficient	(21) $\alpha = (dQ/dt) / A\ dT$	α = heat transfer coefficient; dQ/dt = heat transfer; A = surface area; dT = temperature difference

Altered physiology. Changes in respiratory states like the switch from aerobic to anaerobic conditions and the imposed stress conditions, increased by induction and overproduction of the recombinant protein, lead to shifts in the coupled amino acid biosynthesis, an altered composition of the amino acid pools and changes in the protein biosynthesis machinery (162, 162a, b, c). Even though translation processes are considered to be generally performed precisely [163], the resulting shifts in the amino acid pool in turn lead, due to the inherent inaccuracy of the translation machinery (unspecificity of aminoacyl-tRNA-synthases, "wobbling" of tRNA), to aminoacid misincorporations in freshly synthesized proteins, particularly in phases of high protein production rates, which are characterized by amino acid shortages. Muramatsu et al. [164] report the incorporation of β-methylnorleucin instead of isoleucin into recombinant *E. coli* hirudin in positions 29 and 59. A misincorporation of norvalin instead of leucin and methionine into human recombinant hemoglobin in *E. coli* has been published by Apostol et al. [165] and Kiick et al. [166]. Amino acid misincorporations are thus a cause for an increase of byproducts at the expense of the desired main product yields.

Reduced Plasmid Stability. An essential prerequisite for high product yields particularly in larger scales, in which cultures pass a higher number of generations due to larger culture broth volumes and longer inoculation chains from the cell bank to the production stage, is the stable propagation of plasmids to daughter cells. Plasmid stability is influenced by the plasmid properties, including size and nucleotide sequence; by the genetic background of the host [167, 168]; as well as by process parameters like temperature, growth rates, and substrate concentrations. Lin and Neubauer [169] show that rapid glucose oscillations favor plasmid stability and recombinant protein production rate, whereas high glucose concentrations diminish plasmid stability [170]. Plasmid stability and plasmid numbers are thus negatively influenced, more difficult to control, and less easy to be maintained in larger scales. A concept to render plasmid stability and expression rates more independent from such physiological influences is the application of runaway-plasmids, the replication of which can be induced separately from growth in the desired fermentation phase [171, 172], enabling copy numbers of up to 1000 in the expression phase and, due to the separation of their replication and expression from the growth phase, simultaneously a more precise replication and amino acid incorporation. Further possible measures to enhance the accuracy of metabolic processes are a reduction of the generation time and numbers throughout the process and a deceleration of the metabolic speed, e.g., through reduction of temperature, and the development of more stress-resistant microbial strains.

A prioritized goal of process optimization and scale-up thus consists of an appropriate process design that improves the physiological conditions and the metabolic accuracy by minimizing microbial stress exposure.

1.1.5.2 Process Characterization

To identify process-specific stress factors and to understand the physiological responses to the vessel-specific physical conditions, the mutual influences and interactions of the various physical and physiological parameters have to be analyzed in detail. An overview on the analytical methods currently applied and yet in development is given in the following.

Analytical Methods. Among the physiologically most relevant parameters are, besides the pH as discussed, biomass, cell viability, the concentrations of substrates, metabolites and products, the partial oxygen and carbon dioxide pressures in culture broth, and the composition of the exhaust gas, giving information about respiratory states as indicated, e.g., by the respiratory quotient (RQ; Equation 18, Table 1.1-2). Established analytical methods and tools are colorimetric procedures, chromatography [173], mass spectroscopy [174, 175], enzymatic and electrophoretic methods [176–178], hybridizing techniques, biochips [155, 161, 179], or flow cytometry. Multiparameter flow cytometry permits, in addition to the analysis of usual metabolites, also the analysis of the cellular DNA-, RNA-, and protein content, cell viability, membrane potential, intracellular pH, cell size, and cell development stages [180–183]. In general, the data are, if possible, preferably captured as real-time values by in situ online measurements as occurring for physical parameters [184] to avoid falsified or gappy data due to time differences between sampling and analysis. *Ex situ* methods can be designed as real-time procedures in combination with robust automated sampling and sample preparation methods like ultra-filtration [173, 175, 185] and flow injection analysis (FIA) [173, 186–190]. An online FIA glucose analysis method of the native culture broth without prior sampling and filtration has been presented by Arndt and Hitzmann [191] and Kleist et al. [192]. For their robustness, *in situ* measurements of biological parameters are preferably performed by optical probes (optodes), working either on a physical base, e.g., by refractional or spectroscopic measurements, chemically as by ion exchange reactions [193] or enzymatically by gel-embedded biocatalysts, the activity of which can be measured by means of pH-changes or by fluorophores (chemo- and biosensors) [194, 195]. The hitherto employed enzymes have restricted their application mostly to the analysis of sugar compounds [190], whereby the most frequent applications are reported for glucose [187]. However, despite intensive research, only a few concepts practically applicable for industrial purposes could have been developed. Broader applications are physical optodes enabling the simultaneous measurement and quantification of several parameters and metabolites through continuous scans or excitations and subsequent absorption and scattering measurements within defined wavelength ranges like (1) 2-D-fluorescence spectroscopy [196–198] as shown for the determination of NAD(P)H concentrations through excitation at 350 nm and the fluorescence measurements at 450 nm [190]; (2) near-infrared-spectroscopy (NIR) [199–201], which has been employed as a 700–2500-nm scan in the antibiotic fermentation at Pfizer [202, 203] for the measurement of nutrient and product as well as side product concentrations; or (3) measurements in infrared [204], ultraviolet, or visible wavelength spectra [190]. By means of capacitance measuring electrodes (Aber Instruments Ltd., U.K.), viable cell counts can be performed by seizing the electric capacitance and conductivity of cells with intact membranes in a generated electric field. To gain a picture as comprehensive as possible by enhancing the amount of analyzable substances, multichannel arrays with parallel employment of various analytical procedures monitoring several parameters simultaneously have been established and new concepts like artificial noses [205] and electronic tongues [206] currently being integrated into fermentation technology, allowing the analysis of a large number of analytes by cross-talking semi-specific sensors that act in analogy to the human olphactory sensoric system. The realization of this concept will be facilitated by a

further miniaturization of the sensors and chips employed [207] as it has been achieved with biochips developed for the pharmaceutical natural product screening, onto which the needed number of reactants is fixed in smallest space or is brought together in microchannels and the analytes are separated in microcapillars (lab-on-a-chip-technology) [208–210].

1.1.5.3 Process Optimization

For analysis, interpretation and correlation of the obtained signals and data through chemometric modeling [195, 197], neural network—tools (e.g., Unscrambler 9.0, Camo, Norway)—seem to have gained an increasingly important role [211]. Despite inherent limitations [212, 213], adequately trained neural networks are capable of recognizing and revealing nonlinear, highly complex, and even nonobvious, hidden relations among a multitude of various physical, biochemical, and physiological process parameters and to design the according process models. Hooked up to expert systems, they allow immediate and short-term reactions to process deviations by anticipating physiological drifts and their influences on product yield and quality and to change the according set points and process profiles. In this way, neural network tools help to optimize process control and to facilitate the identification of suitable strategies for process optimization and scale-up, e.g., with respect to an optimized glucose–oxygen equilibrium.

As the maximum glucose and oxygen uptake rates are not constant but depend on growth phases and rates and get reduced by induction of product synthesis [170], Lin et al. [214] established an integrative kinetic model combining these parameters with the aid of the simulation program SCILAB (Inria, F) enabling the determination of the maximum glucose and oxygen uptake rates through determination of the time that passes between glucose pulses and subsequent changes of partial oxygen pressure (pO_2) and biomass concentration. Such a model thus allows the alignment of the glucose feed meeting the maximum uptake capacity and therefore avoiding overflow metabolism. The observed pattern of glucose oscillation even can serve as a key parameter condition in later scale-up stages [169]. The equilibration of carbohydrate and oxygen supply thus constitutes a key component of process control and optimization. Further strategies aiming at the avoidance of oxygen limitation and glucose overflow metabolism consist of the employment of alternative carbon sources like glycerol [215] or galactose [216] and of a drastic glucose restriction. Wong et al. [217] report that minimal concentrations of glucose and yeast extract yielded the highest concentrations of 0.5 and 1 g/L of a recombinant K99 antigen. Yim et al. [218] achieved constant yields of 4.4 g/L of human granulocyte colony stimulating factor during scale-up from 2.5 to 30 L by limiting glucose feed and keeping the growth rate at the minimum ($\mu = 0.116\,h^{-1}$). Besides the above-mentioned parameters like the maximum uptake capacities, the various different physiological or directly measurable physical process parameters like pH, ammonium consumption, pO_2, OTR, or the growth parameters can be applied as a reference parameter for glucose feed in a closed-loop design. Dantigny et al. [219] describe a biomass controlling feed depending on the ethanol formation rate and RQ for *S. cerevisiae*. To achieve a more uniform glucose distribution in large-scale tanks, Larsson et al. [151] and Bylund et al. [152] suggested a glucose feed at the dynamic zones of the fermenter bottom together with the injected air. A step ahead

in this regard would be a further enhancement of the mixing quality by a reactor and process design permitting a multilevel injection of both air and substrates into high turbulence zones.

A supportive approach for comprehension of the large-scale hydrodynamic and reaction conditions to ensure homogenous reaction conditions and to reduce both the size of stress zones and the zonal residence times is the depiction of these zones through transfer into small reactors (scale-down) or through high-performance computing computational fluid dynamics (CFD) [220]. Whereas the sort and amount of parameters that can be simulated by the scale-down approach appear to be restricted, CFD is meanwhile broadly applied, e.g., the flow modeling software tools of Fluent Inc., Lebanon, NH (Fluent 4,5,6 and MixSim). A simulation of the trajectories and distributions of gas bubbles and mass transports enables the determination of zonal pO_2 values and oxygen transfer rates. The combination with parameters like substrate concentrations and gradients, the residence times in the respective zones, population dynamics, and metabolic fluxes (structured metabolic models) leads to integrative models (integrated fluid dynamics, IFD), which permit the prediction of physiological effects and reactions. Even though it is emphasized that the integration of CFD and structured biokinetics currently requires a deeper understanding of the dynamics of metabolic and regulatory networks and cascades of signal transduction triggered by microenvironmental fluctuations and thus further research [221], it will most likely contribute long term to a realistic modeling of the interplay between physics and physiology and thus will facilitate the identification of key parameters influencing product yield and quality the most and therewith of suitable scale-up parameters and strategies. Problems related to the scale-up of physical parameters are illustrated in the next section.

1.1.5.4 Physical Scale-Up Parameters

Suitable for employment as physical scale-up parameters are all known process parameters and coefficients exerting known physiological effects, particularly those affecting oxygen supply; heat transportation and mixing, such as power input (Equation 1; Table 1.1-4), aeration, and agitation rate (Equations 3, 9, and 10; [222]); mixing time (Equation 5; [223]); pO_2; OTR (Equations 14, 15; [224, 225]); oxygen mass transfer coefficient (k_La, Equations 16, 17); and biocalorimetric variables like heat fluxes and heat transfer coefficients (Equations 19, 20, and 21). Biocalorimetric measurements were found to be in definite correlation with metabolic activities and with OTR and are employable as growth phase indicators [226, 227]; the calculations, however, require a precise measurement and knowledge of heat fluxes and sources, energy inputs, and the temperature distribution in the vessel. In most cases, however, it is, depending on the scale-up factor, not, or only restrictedly, possible from the physical viewpoint to keep physical parameters constant throughout the scale-up. Constance of even a single specific parameter mostly leads to an uncontrolled and unpredictable change of other variables into dimensions that are technically not realizable. Classic examples are (1) the mixing time, which inevitably increases in larger vessels due to the larger volumes to be stirred and that cannot be unlimitedly compensated and kept constant by increasing stirrer speeds and energy inputs, and (2) the volumetric energy input P/V. A constant volumetric power input has indeed been successfully applied as a scale-up

parameter for the early industrial penicillin fermentations (1 hp per gallon, equivalent to 1.8 kW per 1 m^3) and in fermentations with low energy inputs [216], but it is limited in fermentations requiring high energy inputs, like recombinant *E. coli* cultures.

For this reason, mathematically driven approaches are pursued for both process and reactor scale-up by forming dimensionless coefficients (e.g., by the Buckingham-Pi method as cited by Hubbard [228]), which are kept constant by an appropriate choice and adjustment of the relevant influencing process and fermenter parameters. Well-established examples are, among many others, the dimensionless power number (Equation 2), Reynolds number (Equation 4), gassing number (Equation 13), and the modified dimensionless power number (Equation 7) and the modified dimensionless mixing time (Equation 8). The comparison of the latter two coefficients and of the corresponding curves enables the identification of appropriate types of stirrers capable of exerting the desired mixing performance at a given stirrer speed with a minimum of energy consumption and therewith to compensate the above-mentioned limitations of volumetric energy inputs at larger scales. (A quantum leap in stirrer technology in this regard seems to be the Visco-Jet of Inotec, which possesses cone-formed short tubes instead of blades and pretends to exhibit the best mixing performance with a minimum of power input and shear stress without foam generation.) The performance of further various types and designs of stirrers is presented and discussed by Junker et al. [229]. Stirrer performance coefficients and curves are thus crucial scale-up aids.

Furthermore, any of these parameters and coefficients can be combined with other variables to set up and create new, process-specific parameter correlations, coefficients, terms, groups, and characteristic curves (examples given, e.g., by Wang and Cooney [230]).

This relates also to the k_La—value (Equation 16), which currently is the most applied physical scale-up variable because it includes the relevant parameters influencing oxygen supply like agitation (via energy input) and aeration as superficial gas velocity (Equation 10) and that, as a component of dimensionless terms, is also frequently employed for reactor scale-up [231].

Taking into account the limitation of a k_La–oriented scale-up in the form of a limited power input, OTR, and tolerable shear stress, Flores et al. integrated the backpressure *p* by maintaining the product of $k_La \times p$ constant through a variation of pressure, agitation, and aeration for scale-up of *Bacillus thuringiensis* fermentations [232]. Although the specific growth was reduced and the biomass production and sporulation efficiency remained constant, fermentation time could be shortened and toxin yields were increased. Wong et al. successfully scaled-up *E. coli* fermentations from 5 L to 200 L by keeping constant the product of k_La and aeration rate (vvm) under variation of power input, working volume, and aeration according to the Wang–Cooney equation (Equation 17; [230]), which reflects these parameters in dependence of the fermentation scale [217]. Diaz and Acevedo [224] argue that the oxygen transfer capacity, indicated by the k_La value, is not the most process-relevant parameter, but the effective oxygen transfer rate as a product of k_La and mass transfer potential is, i.e., the difference between the pO_2-values in the gas and the liquid phase, and suggest an OTR-based scale-up strategy (Equations 14 and 15).

A common, simple and robust method is the maintenance of a constant pO_2 in the culture broth by variation of stirrer speed and aeration rate. To avoid shear

stress and to keep the energy input (P) at the lowest possible level, the pO_2 is steered at the minimum limit. Riesenberg et al. employ a stirrer speed and glucose-feed steered pO_2 of 20% for interferon α–*E. coli*-fermentations in 30-L and 450-L scales [233]. These examples demonstrate that, for each process, appropriate variables and coefficients and therewith scale-up strategies have to be identified individually.

1.1.5.5 Development of Fermentation Models and Strategies

Despite the central role of the scale-up issue in biotechnology and the comparably large body of literature, no common, generally applicable strategy seems to be established. For each product, process, and facility, a suitable scale-up strategy has to be elaborated.

A wholistic scale-up strategy consists of a comprehensive and detailed process characterization to identify key stress factors and key parameters influencing product yield and quality the most, and of an appropriate process control and process design ensuring optimum mixing and reaction conditions, supported by appropriate knowledge and data-driven models [234, 235] as well as computational tools.

It should be kept in mind, however, that any approach and any model will always be approximative and that a compromise in the process-related knowledge will always be gappy and that the known mathematical methods and relations cannot completely reflect the highly complex interactions and relationships of the physical conditions governing the fermentation process [236].

As a matter of fact, it seems, that, in view of the high complexicity of the fermentation parameters influencing each other and the only rudimentary and fragmentary reflection of the reality any model can deliver and finally the different layouts of vessels and facilities that rarely are designed according to strict scale-up criteria, successful scale-up in most cases will not be the result of a conclusive and straight-lined experimental strategy but will be the outcome of an independent optimization on each scale that highly depends on the experience, skill, and last, but not least, intuition of the experimentalist.

To a lesser extent, this also holds true for the design of procedures aimed at the isolation and purification of the compounds from the culture broth. As these purification steps follow upon the biosynthetic steps and the upstream processing in the bioreactor, they are usually referred as "downstream processing."

1.1.6 DOWNSTREAM PROCESSING

1.1.6.1 Product Recovery and Purification

Biopharmaceutical products consist of a multitude of compounds and structures with most having different physical and chemical properties and derive from a large variety of sources like human and animal tissues, body fluids, plant material [237], and as illustrated above, microbial fermentations. Accordingly, purification strategies have to be developed individually and empirically that reflect the physicochemical properties of the product, of the product source, and of potential contaminants by finding appropriate sorts, sequences, combinations, and operation

modes of the respective downstream processing steps to finally achieve high purities and high recovery rates while maintaining the pharmaceutical activity of the molecule.

Traditionally, downstream processing steps are roughly subgrouped into operations related to cell harvest, cell rupture in case of intracellularly occurring products, product capture, product purification, and product polishing to manufacture a drug ready for galenic preparation and consist of a sequence of solid–liquid separation and solvent and solid-phase extraction steps. Large-scale cell harvest usually occurs by preparative centrifugation, e.g., in a decanter or in disk stack separator or by filtration to simultaneously separate existing suspended particles from the surrounding broth. Fragile mammalian cells are usually separated by filtration methods only.

If the value product occurs intracellularly, the slurry is taken up in washing buffers of appropriate ionic strength for preparation of the cell rupture, which occurs, e.g., by high-pressure homogenization, sonification, bead milling, or enymatic procedures.

Product capture is defined as the first product extraction and purification step aimed at a product concentration by volume reduction and partial purification, whereas polishing constitutes the final purification step, which removes persistent residual minor impurities like denatured, aggregated, or nonfunctional isoforms of the product, and which follows the preceding (intermediate) purification steps aimed at the removal of contaminating solutes like host cell proteins, DNA, and media components. Product capture usually starts with precipitation, solvent extraction, and/or a cascade of ultra-filtration and nano-filtration steps before the first ion exchange or size exclusion chromatography. Antibodies and antibody derivatives, which account for about 20% of the biopharmaceutical products currently in development, are preferably bound to affinity matrices [238] by natural immunoglobulin-binding ligands such as the *Staphylococcus aureus* membrane and cell wall protein A [239] or the streptococci surface protein G. To broaden the availability of specific structures with suitable binding properties, synthetic ligands with enhanced stability and resistance to chemical and biochemical degradation are continuously attempting to be developed, supported, e.g., by computer-aided design. The development of synthetic ligands with enhanced selectivity and stability, tailored to specific biotechnological needs and product structures, will lead to more efficient, less expensive, and safer procedures not only for purification of antibodies but also for other proteins at manufacturing scales. Also, antibodies can be employed as a means for protein purification in the form of immunoaffinity chromatography [240]. A novel emerging technology is the use of synthetic single-stranded nucleic acid molecules (aptamers) as affinity ligands [241], which fold up into unique three-dimensional structures specifically binding to the desired target structure as it has been shown for the purification of thyroid transcription factor or selectin receptor globulin [242, 243].

The subsequent purification steps including polishing are mostly performed on hydrophobic interaction resins and/or on reversed-phase matrices.

1.1.6.2 Downstream Processing Optimization and Economization

Mostly due to the tremendous costs of sometimes several thousand € per liter for chromatographic resins and production scales of up to several hundred liters column

volume and due to the prices for the columns themselves of up to hundreds of thousands of U.S. dollars, downstream processing expenses account for the largest part (50–90%) of the total production costs and are therewith a focal area for process economization attempts. One of the many criteria for the choice of a resin is its shelf life. Bearing in mind that every downstream processing step coincides with a minimum product loss of 5–10%, the removal of a particular step not only helps to save the respective capital investment, but concomittantly to increase the final product yields, and thus to render the whole production process more economical in several respects. To reduce the number of required steps, a selection has to be made for resins exhibiting excellent separation, resolution, and yield with respect to a given product and the contaminants, i.e., for resins exhibiting excellent product binding selectivity and capacity. Likewise, the operation mode of the column has to be optimized with respect to the specific product load, adjustment of the physico-chemical operational conditions like pressure, temperature, pH(-shift), ionic strength, and sort of buffers and eluents (e.g., evaluation of continuous vs. step gradients).

A further approach is the combination of the solid–liquid separation and product recovery into a single step, e.g., by expanded bed adsorption [244, 245], which permits the direct initial purification from culture broths without the need of prior removal of suspended solids. In contrast to the conventional column operation, the mobile phase is pumped upward through the column bed from beneath. The bed thus starts to expand at a liquid flow rate above a critical value, and the gaps between the sorbent beads expand. The controlled distribution of bead size and bead weight results in a stable expanded bed in which the beads oscillate around a steady position and thus avoid clogging of the column. Whereas preparative liquid chromatography methods [246] have become a well-established separation and purification method in the pharmaceutical industry, techniques like two-phase system partitioning [247] and its variant reverse micellar extraction [248], which also potentially offer advantages like the possibility of a direct extraction from the culture broth through partitioning of the compounds into two immiscible phases, need further developmental activities for economic large-scale applications in the production of biopharmaceuticals and are less common.

A further criterion for the choice and design of a downstream processing procedure is thus its scalability.

1.1.6.3 Downstream Processing Scale-Up

Comparable with the scale-up of fermenters and fermentation processes, the scale-up of downstream processes, particularly of column and column operation, is not simply a matter of increasing size. Increasing column diameters, reducing the stabilizing wall effects, and increasing resin bed heights may lead to an altered settling behavior of the beads, to channel formation through shrinking and swelling of the packed matrix, to column clogging with a concomittant reduction of the flow rates and an increase of the column back pressure, to altered hydrodynamic behavior and residence times of the process fluids, and to an altered pattern for the product/contaminants adsorption/desorption pattern [249]. To avoid the resulting quality impairments and deviations, resins with a suitable scale-up behavior have to be selected and the resin bed height is tried to be kept constant as far as possible as

is the flow rate as key scale-up parameters, which requires an appropriate experimental design in early laboratory development stages. As this, however, is only possible to a limited extent, downstream processing scale-up also is the result of an optimization of the respective operation conditions (see above) on each scale.

A procedure that has been optimized for decades and scaled-up to dimensions of several cubed meters is the commercial β-lactam purification.

(For further general articles dealing with problems and issues of downstream processing, the reader is referred to the reviews in Refs. 249–255).

1.1.6.4 Downstream Processing of β-Lactam Compounds

As most of the product is secreted and is thus concentrated in the culture broth, the recovery process starts with filtration, usually with a rotary vacuum filter, followed by a cascade of solvent and solid-phase extraction steps.

Common penicillin extraction solvents are amyl- and butyl-acetate or methylisobutylketone. As penicillin is extracted as a free acid at pH 2–2.5 and the molecule is instable at this pH, extraction occurs in a counter-flow using Podbielniak- and Luwesta-centrifugal extractors to shorten the contact time with the solvent and to prevent product decomposition.

Purification is through subsequent and repeated crystallization from an aqueous solution after alkalization.

In contrast to penicillin, the hydrophilic cephalosporin is more suitable for solid-phase extraction. For high yield and purity extraction, a combination of several, different chromatographic steps is used.

Hydrophobic interaction chromatography on neutral polyaromatic resins like Amberlite XAD 4, 16, 1180, or Diaion HP20 is widely used in combination with weak basic anion exchangers like Diaion WA-30 or strong acidic cation exchangers like Amberlite XAD 2000 and Diaion SK-1B [256, 257]. The mentioned resins are recognized for their high sorption capacity and their long shelf life.

Whereas the improvements on the extraction level are less spectacular, significant progress over the last few years can be noticed with respect to side-chain cleavage to 6-aminopenicillanic acid (6-APA) and 7-aminocephalosporanic acid (7-ACA) in switching from chemical to enzymatic procedures.

1.1.7 POSTSYNTHETIC STRUCTURE MODIFICATION

Most antibiotics in therapeutic use are synthesized or modified exclusively by the means of chemistry and are derived from the established compound classes, which have been known for decades. Chemical derivatization thus has also been applied to substances that are of microbial origin and that therefore are termed semi-synthetic.

Among the most recent semi-synthetic antimicrobials are Aventis' streptogramin derivative Synercid and the erythromycin derivatives clarithromycin (Klacid) from Abbott (Abbott Park, Illinois) and roxithromycin (Rulid) and the brand new ketolide telithromycin (Ketek), both from Aventis (Paris, France) [86].

Despite these recent successes and increasing efforts, the yields of therapeutically useful entities emerging from such chemical derivation programs are continuously decreasing.

For this reason, large-scale derivation methods (combinatorial chemistry) are integrated in the search for innovative antibiotics as are biotechnological approaches for structure modification. Biocatalytic procedures, which have been shown to be useful for generating novel antibiotic structures like Loracarbef, a novel β-lactam compound from Eli Lilly (Indianapolis, Indiana) highly active against various β-lactamase producing species [258, 259], are also about to replace continuously chemical production processes. At several universities and corporations, screening studies have been initiated to find appropriate enzymes for compound conversions, as it has been successfully established in production processes for penicillin and cephalosporin. (A review discussing criteria like resource and energy consumption, emissions, health risk potential, area use, and environmental effects for the evaluation of the eco-efficiency of biotechnological processes is given by Saling [260]).

1.1.7.1 β-Lactam Side-Chain Cleavage

6-APA and 7-ACA as the key intermediates for the production of semisynthetic penicillins and cephalosporins (see Section 1.1.3.2) are obtained by removal of the acyl side chains.

There is a large body of patents existing for chemical and enzymatic splitting procedures, but enzymatic processes have been more successful for economical as well as for ecological reasons.

Enzymatic 7-ACA splitting procedures [for general review, see 261] have been developed and commercialized by companies like Asahi Chemical, Hoechst, and Novartis. The replacement of the hitherto employed chemical deacylation processes like the imino ether (Figure 1.1-3) or the nitrosyl chloride method [262] resulted in a cost reduction of 80% and a decrease of the waste volume by a factor 100 from 31 t to 0.3 tons per 1-ton 7-ACA. Chlorinated hydrocarbons like dimethyl aniline and methylene cloride as well as heavy metal ions can be completely avoided. Instead of zinc salt formation, multiple silylation, formation of the imino chloride, imino ether, and finally an imino ether hydrolysis, the side chain is removed in two enzymatic steps (Figure 1.1-3).

Cephalosporin C is first oxidized and deaminated by a D-amino acid oxidase (DAO), which can be obtained from various fungal species, like the yeasts *Trigonopsis variabilis* and *Rhodotorula gracilis* or the ascomycete *Fusarium solani*. The resulting α-keto-adipyl-7-ACA, upon decarboxylation, is converted into glutaryl-7-ACA (G-7-ACA). DAO is a flavoenzyme containing flavin adenine dinucleotide as the prosthetic group and catalyzes oxidation of D-amino acids to their corresponding keto acids. In a second step, the glutaryl side chain of G-7-ACA is deacylated by a glutarylamidase from *Pseudomonas diminuta* [263]. The molecular data of other potentially suitable enzymes and genes from various sources are given by Isogai [264]. It is noteworthy that the enzymatic splitting process could have only been rendered economical and therefore commercially employable through a significant increase of glutarylamidase yield on the fermentation level by using a gene-recombinant *E. coli*-strain.

A recombinant amidase from *E. coli* is also the most commonly employed enzyme for 6-APA production by deacylation of penicillin G [265], a process that has been established now for decades [266]. With an annual turnover of 30 tons, the *E. coli* penicillin amidase is one of the most widely used biocatalysts, despite

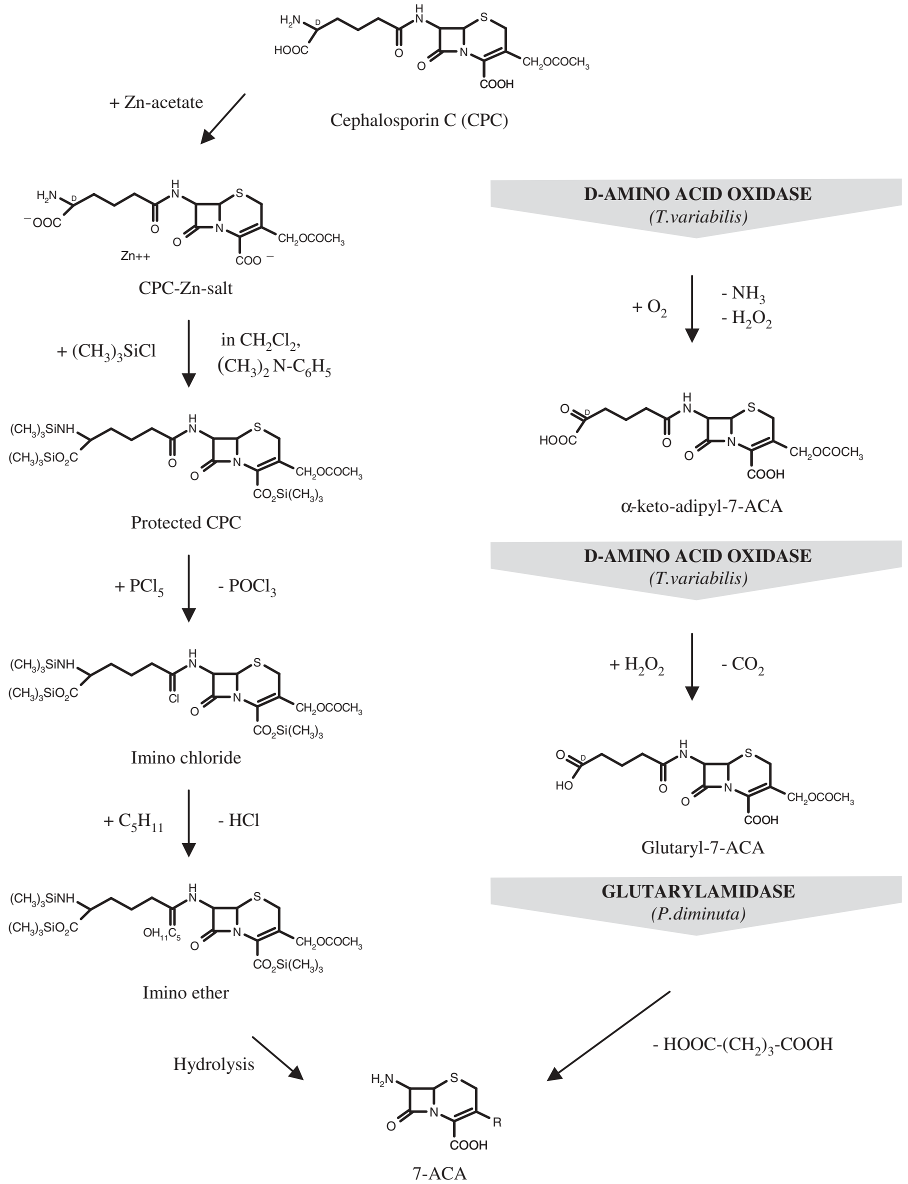

Figure 1.1-3. Replacement of the chemical cephalosporin C splitting procedure by a biotechnological process. Biotechnological production and derivatization procedures are continuously being developed to replace chemical processes for both economical and ecological reasons. An established industrial process is the enzymatic splitting of cephalosporin C to 7-ACA by D-amino acid oxidase of the yeast *Trigonopsis variabilis* and a glutarylamidase of *Pseudomonas diminuta* (right) replacing the chemical imino ether method (left). For further details, see text. (Graph taken from Ref. 98, © Springer-Verlag.)

the discovery of further similar acting enzymes from various microbial sources, including penicillin V acylases [267] from the basidiomycetes *Bovista plumbea* [268, 269] and *Pleurotus ostreatus* [270]; from the ascomycete *Fusarium* [271]; or from the yeast *Cryptococcus*.

A significant milestone in economization of enzymatic β-lactam production has been reached by enzyme immobilization permitting a preservation and multiple use of the cleavage enzymes. The currently most employed resins in industries for this purpose are epoxyacrylic acids (Eupergit) and silica gel derivatives (Deloxan). The general economic criterion for the preparation of a biocatalyst is production costs in relation to yield, turnover rate, storage stability, and operational/mechanical stability. Further criteria are outlined in the *Guidelines for the Characterization of Immobilized Biocatalysts* by the European Federation of Biotechnology. Application criteria are filterability, sedimentation velocity, and particle firmness. Operational and storage stability as well as the activity of this biocatalyst and the quality of 6-APA with respect to color are improved by sulfur reducing compounds [272]. As pointed out, the ensurance of product quality and drug safety is a key issue in pharmaceutical production processes.

1.1.8 QUALITY ISSUES

According to regulatory requirements, pharmaceutical production facilities and processes have to be proven to function properly across the entire range of process critical parameters by a qualification of the facilities and equipment, which consists of the steps design qualification (DQ), installation qualification (IQ), operational qualification (OQ), and performance qualification (PQ) and which results in a validation of the production process to substantiate that the complete system is capable of manufacturing the respective product reproducibly in a consistent quality as expected within preset specifications and in compliance with all laws and guidelines, like the cGMP (current good manufacturing practice) regulations, among others, issued by regulating authorities like the FDA and European Medicines Agency (EMEA).

The products have to be sterile and free of any contaminations that might derive from process material, residues of preceding production campaigns (cross-contaminations) in the case of product changes, and of the agents used for facility cleaning. To restrict the introduction of such contaminations into the repective production steps, the production facilities, equipments, and solutions are usually cleaned according to validated cleaning procedures (e.g., with 1 M NaOH) and sterilized by heat or filtration before their use. Product sterility is achieved by aseptical performance of the last manufacturing steps and by micro-filtration (0.2 μm) or, if possible, by terminal heating of the product before filling. Residues of chemical cleaning agents are removed according to validated procedures by rinsing with purified water.

As biopharmaceuticals are potentially contaminanted with possibly harmful viruses and allergenic and pyrogenic acting endotoxins as residual components of their host cell, guidelines and directions have been issued by the FDA's Center for Biologics Evaluation and Research (CBER) requesting validated procedures for virus and endotoxin removal and inactivation.

1.1.8.1 Virus and Endotoxin Removal

Endotoxins, which consist of the lipopolysaccharide fraction present in the cell wall of gram negative germs and which tend to adhere to equipment surfaces and to persist in products and product solutions, as do viral contaminants deriving from cell culture processes or from starting plasma or tissue material, can also be efficiently removed by final filtration steps. Whereas ultra-filtration with a cut-off of or below 10 kDa is sufficient for endotoxin removal, viruses need to be removed by nano-filtration steps complemented by a variety of inactivation measures like pasteurization, pH inactivation, solvent/detergent treatment, or ultraviolet and gamma ray irradiation. Usually, endotoxins and viruses are already deconcentrated to a significant extent by the chromatographic steps and the solvent exposure in the course of the normal purification procedures [251].

1.1.9 CONCLUSION

Marching in step with the technical and methodological progresses, biotechnology is gaining in increasing importance in pharmaceutical production processes by replacing chemical production procedures for economical and ecological reasons and in the development and commercialization of novel therapeutic principles.

To fully exploit the potential of biotechnological production methods, an integrated process design will be necessary considering the downstream processing requirement during the design of upstream operations and vice versa (A comprehensive overview illustrating the complete biotechnological production chain is given in Table 1.1-3.) As the fate of a compound as a pharmaceutical also depends on the prospective production costs already estimated in the development phase and production processes cannot be significantly changed after approval without running the risk of having to perform ad-ditional clinical trials, it is of utmost importance to choose and design production organisms, strains, vectors, expression cassettes, and fermentation procedures as early as possible in compliance with the prospective harvest and purification methods also to be chosen and designed according to cost criteria. Integrative biotechnology thus is not only a key prerequisite for the development of competitive and economical production processes to relieve the downward price pressure applied by generic drug makers after patent expiration and for the acceleration of market approval for new drugs in the highly competitive environment of the biopharmaceutical industry, but also it is a key technology to save and liberate capital for the development of novel drugs for the benefit of mankind.

1.2.1 SUMMARY OF THE CHAPTER

An almost complete sequence of the human genome is available now, and progress in the sequencing of other model organisms is impressive. This sequence information provides enormous possibility for identification of disease genes. The first step for sequencing of large genomes usually is the construction of a high-resolution, long-range physical map based on sequence tagged site (STS) markers. Using this map, the contig of overlapping clones is constructed and sequenced. This strategy (hierarchical) was used by the International Human Genome Sequencing Consortium to sequence the human genome. The second approach, the whole genome sequencing (WGS) strategy, was used by researchers from Celera Genomics. This strategy, in principle, doesn't need construction of high-resolution physical map and is based mainly on shotgun sequencing of large and small insert clones.

Unfortunately, both strategies for mapping and sequencing are not appropriate for the challenge of high-throughput comparative genomics. Alternative and complementary strategies need to be developed, and the imperative now is to find cost-effective and convenient methods that allow comparative genomics projects to be performed by a wide range of smaller laboratories. Recently developed novel techniques open new perspectives for nonexpensive and fast sequencing. These novel developments can be grouped into two classes. The first type of improvement is enormous, increasing the speed and throughput of producing sequences. These techniques are based on massively parallel sequencing approaches (MPS and "494" techniques) where billions of individual DNA molecules could be sequenced simultaneously. Another type of improvements is a recently suggested completely different and efficient strategy for simultaneous genome mapping and sequencing. The approach is based on physically oriented, overlapping restriction fragment libraries called slalom libraries. Both techniques allow increasing the speed and decreasing the cost of sequencing 10–100 times. Importantly, they can be combined to increase efficiency even more.

1.2.2 DEFINITIONS OF KEYWORDS

Adaptor—an oligonucleotide that after ligation to a DNA molecule confers to it specific features.

Allele—is one of several alternative forms of a gene (or in the wider sense of any region of the chromosomal DNA) that occupies a given locus of chromosome.

Cap—the chemical modification at the 5′-end of most eukaryotic mRNA molecules.

Centromere—the region of a chromosome where the pairs of chromatids are held together.

Clone contig—a collection of clones (i.e., vectors or cells containing the same recombinant molecule) whose DNA inserts overlap.

Coding RNA—an RNA molecule that codes for a protein (mRNA).

DNA sequencing—establishing the order of nucleotides in a DNA molecule.

Episome—a vector or DNA sequence that can exist as an autonomous extrachromosome replicating DNA molecule.

Exon—a coding region within a discontinuous gene.

Genetic selection—in cloning, this usually means selection against parental, nonrecombinant molecules in favor of recombinant ones. SupF selection exploits vectors carrying *amber* (nonsense mutation UAG) mutations (*ochre* is a nonsense mutation UAA). These vectors cannot replicate without the supF gene, which must be present either in the host or in the cloned insert. If the insert carries the supF gene, only recombinant phages will be able to replicate in an *Esherichia coli* host without the suppressor gene.

Intron—a noncoding region within a discontinuous gene.

Kilobase pairs (kb)—1000 base pairs.

Ligation—formation of a 3′–5′ phosphodiester bond between nucleotides at the end of the same or two different DNA or RNA molecules.

Marker—a gene or just DNA fragment that was located on a genome map.

Megabase pairs (Mb)—1000 kb.

Polylinker—a short DNA fragment (in the vector) that contains recognition sites for restriction enzymes that can be used for cloning DNA fragments into this vector.

Restriction enzyme—an enzyme that recognizes a specific sequence in DNA and can cut at or near this sequence. In cloning procedures, the most commonly used enzymes produce specific protruding (sticky) ends at the ends of a DNA molecule. Each enzyme produces unique sticky ends. The DNA molecules possessing the same sticky ends can be efficiently joined with the aid of DNA ligase (see **Ligation**).

STS—sequence tagged site. This is a short (200–500 bp) sequenced fragment of genomic DNA that can be specifically amplified using polymerase chain reaction (PCR) and represent or is linked to some kind of marker (i.e., it is mapped to a specific locus on a chromosome).

Shot-gun approach—a sequencing strategy for when a large DNA molecule is randomly broken, cloned, and sequenced. The final sequence of a DNA molecule is assembled by a computer program.

Telomere—the end of a eukaryotic chromosome.

1.2.3 INTRODUCTION. SHORT HISTORY OF THE HUMAN GENOME PROJECT

The Human Genome Program (HGP) was suggested and widely discussed within the scientific community and public press during the mid-1980s and over the last half of that decade [1–4]. In 1985, Dr. Charles DeLisi, then Associate Director for Health and Environmental Research at the Department of Energy (DOE) began to discuss an unprecedented biology project—to sequence the complete human genome. DOE funding began in 1987. The National Institutes of Health (NIH) established the Office of Human Genome Research in September 1988. The Director of this Office (renamed the National Center for Human Genome Research, NCHGR) was Dr. James Watson. The Human Genome Initiative was proposed to the Congress of the United States in 1988 by James Watson, initiating a worldwide coordinated research activity to sequence the DNA of humans and several other test organisms. In the United States, the (DOE) initially, and the NIH soon

thereafter, were the main research agencies within the U.S. government responsible for developing and planning the project. By 1988, the two agencies were working together, a relationship that was formalized by the signing of a Memorandum of Understanding to "coordinate research and technical activities related to the human genome." The initial planning process culminated in 1990 with the publication of a joint research plan. The HGP started in 1990 as a 15-year program. One of its main coordinators was Dr. Francis Collins, Director of the National Human Genome Research Institute (NHGRI) at the NIH. Soon, the Human Genome Organization (HUGO) spread to Europe (HUGO Europe) and Japan (HUGO Pacific) to coordinate the research performed in other countries outside of the United States. The HGP was an international research program designed to construct detailed genetic and physical maps of the human genome, to determine the complete nucleotide sequence of human DNA, and to localize the estimated 50,000–100,000 genes within the human genome. The similar analyses on the genomes of several model organisms were also planned to be performed. The scientific products of the HGP were suggested to comprise a resource of detailed information about the structure, organization, and function of human DNA, information that constitutes the basic set of inherited "instructions" for the development and functioning of a human being. Achievement of the ambitious aims of HGP would demand the development of new technologies and necessitate advanced means of disseminating information widely to scientists, physicians, and others in order that the results may be rapidly used for the public good. Important for the success of the HGP was the statement that a fraction of the project money should be devoted to the ethical, legal, and social implications of human genetic research. It was clearly recognized that acquisition and use of such genetic knowledge would have momentous implications for both individuals and society and would pose several policy choices for public and professional deliberation. The HUGO program aims at a detailed understanding of the organization of the human genome, to enable a molecular definition of the basis for normal function as well as genetic disorders affecting human cells and the organism as a whole. An intermediate aim in this program was the construction of a high-resolution physical map for the human genome. At the beginning of this work, with sequencing still slow and expensive, the HGP adopted a "map–first, sequence later strategy." In the early 1990s, two Parisian laboratories, the Centre d'Etude du Polymorphisme Humain and Genethon, had an integral role in mapping of the human genome. The laboratories' driving forces were Drs. Daniel Cohen and Jean Weissenbach. Later the genome project constructed a higher resolution map that was used to sequence and assemble the human genome. In July 1995, a team led by Dr. J. Craig Venter published the first sequence of a free-living organism, *Haemophilis influenzae* (1.8 Mb) [5]. In October 1996, an international consortium publicly released the complete genome sequence of the yeast *Saccharomyces cerevisiae* (12 Mb) [6]. In May 1998, Venter announced a new company named Celera and declared that it will sequence the human genome within 3 years for $300 million. In December 1998, Drs. John Sulston, Robert Waterston, and colleagues completed the genomic sequence of *Caenorhabditis elegans* (100 Mb) [7]. The first complete human chromosome sequence—number 22 (33 Mb)—was published in December 1999 [8], and in June 2000, leaders of the public project and Celera announced completion of a working draft of the human genome sequence. Finally, in February 2001, the HGP consortium

published its working draft of the human genome sequence in *Nature* and Celera published its draft in *Science* (2.9 billion bp) [9, 10].

1.2.4 VECTORS. DESCRIPTION OF THE MAIN TYPES OF VECTORS USED IN THE HGP

In this section, common vectors used for everyday cloning and subcloning like plasmid and M13 vectors will not be discussed. Only vectors suitable for cloning relatively large DNA inserts will be mentioned with the exception of lambda phage-based vectors specially designed to clone cDNA.

1.2.4.1 Lambda-Based Vectors and Main Approaches to Construct Genomic Libraries

Numerous modifications have been made to bacteriophage lambda-based vectors to facilitate their handling and to extend their use for new types of biological experiments [11–15]. The application of each vector is usually limited to a specific task: the construction of general genomic libraries that contain all genomic DNA fragments or special genomic libraries that contain only a particular subset of genomic DNA fragments. Among these special libraries, NotI linking and jumping libraries have particular value for physical and genetic mapping of the human genome.

Despite their obvious advantages for special purposes, novel vectors (YACs, BACs, PACs; see below) cannot compete with lambda-based vectors for ease of handling, screening, amplification, and biological flexibility, due to the almost complete knowledge about phage lambda genes and biology. The easiest way to obtain a maximal proportion of recombinant molecules is to perform ligation at a high concentration of vector and insert (genomic) DNA because an elevated concentration of DNA facilitates intermolecular ligation instead of self-ligation of the vector's molecules. In this case, the main product is long DNA chains (>200 kbp) containing many copies of vector and genomic DNA fragments. Extremely efficient *in vitro* systems for packaging such DNA into lambda phage particles (10^9 plaque-forming units per microgram of DNA) to produce viable phages were developed and are commercially available.

Extensive modifications of lambda phage vectors were developed that combine the features of different vector systems (see Figures 1.2-1 and 1.2-2, [13–15]).

Cosmids are essentially plasmids that contain the *cos* region of phage lambda responsible for packaging of DNA into the phage particle. Any DNA molecule, containing this region and having a size between 37.7 kb and 52.9 kb, can be packaged into phage particles and introduced into the *E. coli*. The advantages of cosmids are their easy handling (as with plasmids) and big cloning capacity. As the plasmid body is usually small (3–6 kb), large DNA molecules (46–49 kb) can be cloned in these vectors.

Phasmids are lambda phages that have an inserted plasmid. They have the same basic features as lambda phage vectors, but inserted DNA fragment can be separated from the phage arms DNA and converted into a plasmid form. There are two main ways for such conversion: biological and enzymatic. In the first case, the

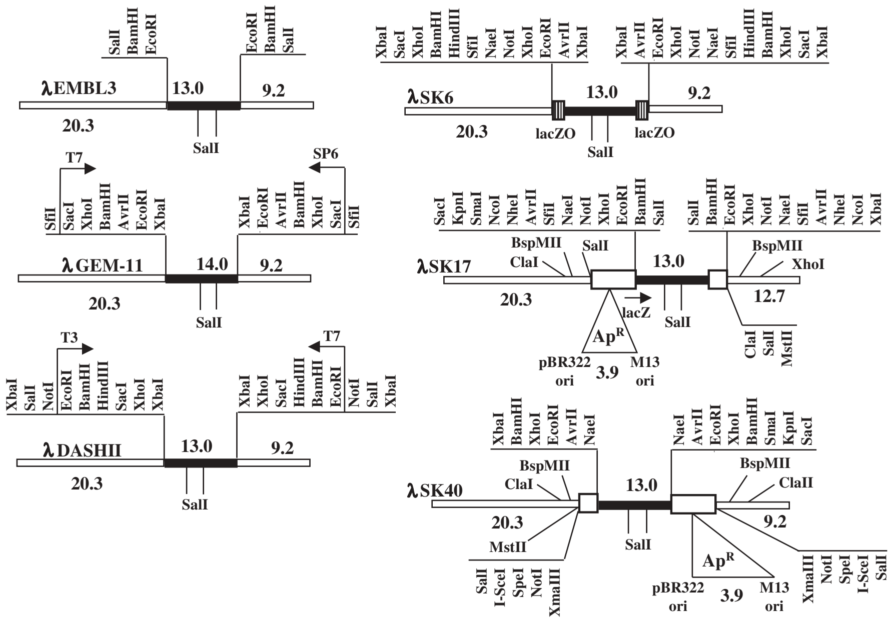

Figure 1.2-1. Examples of vectors used for construction of genomic libraries (maximum capacity 24 kb). Standard λ vectors (λEMBL3, λGEM11, λDASH, λEMBL3, and λSK6) and diphasmid vectors (λSK17 and λSK40) are shown. Sizes are in kilobases and are not shown in the scale. Not all restriction sites are shown. Heavy thick lines represent stuffer fragments; open boxes mark plasmid and M13 sequences; *lacZO* is the *lac* operator sequence. T3, T7, SP6-promoters for T3, T7, and SP6 RNA polymerases.

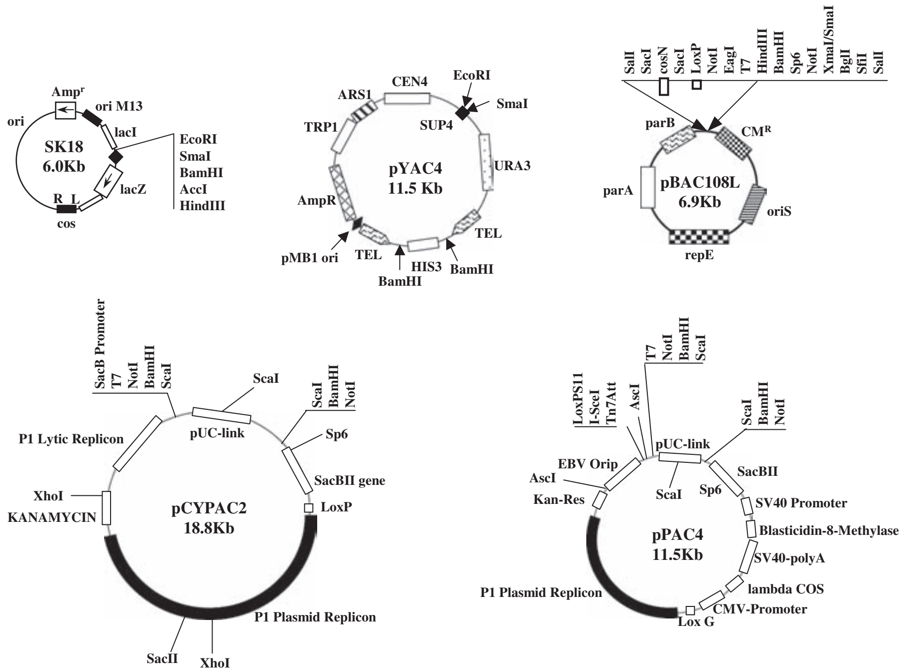

Figure 1.2-2. Examples of vectors used for construction of genomic libraries (capacity more than 45 kb). Sizes are in kilobases and are not shown to scale. Not all restriction sites are shown. For more details, see the text.

phasmid vector contains signal sequences bordering the insert and plasmid body in the phage vehicle. These signal sequences (e.g., from P1, lambda, M13 phages) can be recognized by specific proteins (e.g., *cre*-recombinase), and the cloned DNA fragment together with plasmid body will be cut out [16, 17].

The enzymatic conversion (see, for example, SK17 and SK40 vectors in Figure 1.2-1) can occur if the inserted DNA fragment and plasmid sequences are placed between two recognition sequences of some rare-cutting restriction endonuclease (e.g., I-SceI enzyme that recognize 18 bp and probably does not have any recognition site in the human genomic DNA). This enzyme can be used to separate the cloned DNA fragment together with the plasmid sequences from phage arms. Self-ligation of the molecules with insert and plasmid sequences will result in the production of a recombinant plasmid that can be introduced into the *E. coli* host.

Diphasmids combine the advantages of lambda and M13 phages, and plasmids, i.e., the three main types of vectors used in everyday molecular cloning. They can be divided into two classes: (1) diphasmids that can replicate as phage lambda (a further improvement of phasmids); see SK17 in Figure 1.2-1; and (2) diphasmids that are not able to replicate as phage lambda, i.e., a cosmid that can be packaged into phage M13 particles, e.g., SK18 in Figure 1.2-2.

In some cases, it is more convenient to work with a genomic library in plasmid than in lambda phage form. The construction of representative genomic library directly in a plasmid vector has several drawbacks and difficulties. However, these problems can be easily solved with the help of phasmid and diphasmid vectors. In this case, a genomic library is constructed in lambda phage (e.g., SK40), and then the whole library is converted to plasmid form.

Although the work with different lambda-based vectors is very similar, vectors for construction of genomic and cDNA libraries still have some special features. The major difference between cDNA and genomic cloning is the size of insert: short for cDNA and long for genomic fragments. Due to this difference, it is obvious that the enzymatic way of transferring inserts into the plasmid form is more dangerous (with the respect to the representativity of the library) for genomic libraries than for cDNA, because the probability that the insert contains a recognition site for the particular restriction enzyme increases with the length of the DNA insert. Most of cDNA vectors are "insertion" vectors, and genomic vectors are "substitution" vectors, which means that inserted foreign DNA fragments replace the stuffer vector fragment that does not have any important replicative function.

Full-length cDNAs are the most important material for the identification of all human genes. Cloning of full-length cDNA inserts has been hampered by problems related to both the preparation and the cloning of long cDNAs. Part of the difficulty associated with the preparation of long cDNAs has been overcome with the introduction of a thermostabilized and thermoactivated reverse transcriptase and the development of cap-based full-length cDNA selecting techniques. In contrast to standard cloning techniques, full-length cDNA cloning has the inherent risk of the under-representation or absence of clones corresponding to long mRNAs in the libraries, because the truncated cDNAs are usually not cloned. However, even in a perfect full-length cDNA library, cDNAs deriving from very long mRNAs will not be cloned if the capacity of the vector is insufficient. The most available cloning vectors show bias for short cDNAs: Shorter fragments are cloned more efficiently than the longer because of the intermolecular competition that occurs at the

ligation and library amplification steps. To solve this problem, substitution vectors for cDNA cloning were designed.

For conversion into the plasmid form, the biochemical approach for SK-vectors was used [14]. Some vectors, like SK16 and SK17, have a cloning capacity of 0.2–15.4 kb and others, for example SK23, could be used for cloning of 3.7–18.9-kb inserts only. These cDNA vectors retain the most important advantages of the genomic vectors, e.g., the possibility of biochemical selection when producing vector arms and genetic selection against nonrecombinant phages. Importantly, the libraries made in some of these SK-vectors can be used as both expressed and nonexpressed libraries. For instance, libraries constructed in SK16 would be expressed only in *E. coli* strains containing *ochre*-codon mutation, and SK17 has *amber*-codon-controlled expression of cDNA.

In lambda FLC (full-length cDNA cloning), cloning capacity is either 0.2–15.4 kb or 5.7–20.9 kb. In these vectors, *cre*-recombinase mediated excision was used [17]. The average size of the inserts from excised plasmid cDNA libraries was 2.9 kb for standard and 6.9 kb for size-selected cDNA. The average insert size of the full-length cDNA libraries was correlated to the rate of new gene discovery, suggesting that effectively cloning rarely expressed mRNAs requires vectors that can accommodate large inserts from a variety of sources without bias for cloning short cDNA inserts.

One of the most important features of a genomic library is a representativity. A representative genomic library means that every genomic DNA fragments will be present at least in one of the recombinant phages of the library. In practice, however, this is difficult to achieve. Some genomic fragments are not clonable because of the strategy used for construction of the genomic library. In other cases, genomic DNA fragments (contain poison sequences) can suppress the growth of the vector or the host cell so its cloning can be restricted to specific vector systems. The important reason for the decreased representativity is different replication potential of different recombinant vectors. Thus, amplified libraries have significantly worse representativity. Usually a library is considered to be representative if after the first plating (before amplification) it contains several recombinant clones together containing genomic DNA fragments equal to a 7–10 genome equivalent. The way in which the genomic DNA fragments are produced for cloning is also important. The more randomly the genomic DNA is broken, the more the representative library can be obtained. Clearly, the EcoRI enzyme (6-bp recognition site) will cut genomic DNA less randomly than Sau3AI (4 bp recognition). Probably, the shearing of DNA molecules using physical methods (sonication, shearing using syringe) is the most reliable way to obtain randomly broken DNA molecules.

There are many different modifications to construct libraries; however, the three ways to construct genomic libraries are the most commonly used and will be exemplified below using genomic lambda-based vectors (Figure 1.2-3, [12–14]).

The classic method includes generation of sheared genomic DNA fragments using physical or enzymatic fragmentation followed by the physical separation of fragments of a particular size using, for example, ultra-centrifugation or gel-electrophoresis. The vector DNA is digested with two (or even three) restriction enzymes; those recognition sites are located in the polylinker. The arms and the stuffer fragment are purified, and on the further steps, arms/stuffer would be not able to ligate because they have different sticky ends, preventing recreation of the original vector molecules during subsequent ligation with genomic DNA fragments.

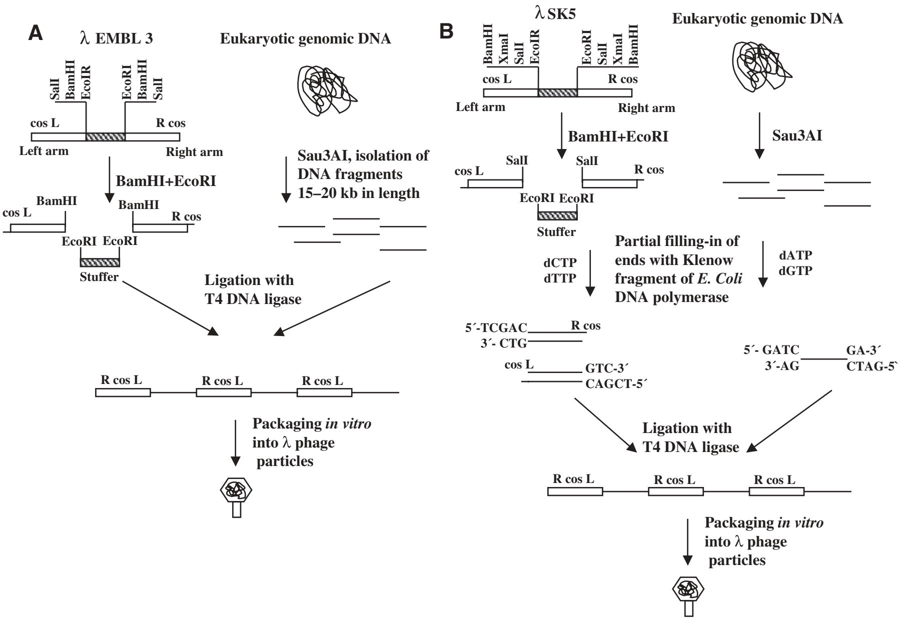

Figure 1.2-3. Two main approaches for construction of genomic libraries: (a) classic method and (b) partial filling-in method. cosL and Rcos—left and right parts of the *cos* site, respectively.

In the "dephosphorylation" approach [18, 19], the phage arms are prepared as described above. Genomic DNA is partially digested to obtain DNA fragments with sizes in the desired range; i.e., for the lambda vectors FIXII and SK6, it is 15–22 kb. These DNA fragments are dephosphorylated (which prevents their ligation to each other) and then ligated to the vector arms.

The third, "partial filling in" method [20], also avoids fractionation steps (Figure 1.2-3B). Phage arms are prepared by double digestion as described before (in this particular case, SalI and EcoRI are shown, but many other combinations can be used), and the sticky-ends produced after digestion are partially filled-in with the Klenow fragment of DNA polymerase I (or other DNA polymerase) in the presence of dTTP and dCTP. Genomic DNA partially digested with Sau3AI is also partially filled-in but in the presence dATP and dGTP. Under these conditions, self-ligation of vector arms or genomic DNA is impossible.

1.2.4.2 YACs

The mapping and analysis of complex genomes require vectors that allow cloning and work with large DNA fragments. Lambda-based vectors have many advantages as described above; however, a comparatively small size of inserts (maximum 48–49 kb) complicates the use of these vectors for the mapping of complex genomes.

Technological improvements made the cloning of large DNA pieces possible using artificially constructed chromosome vectors that carry human DNA fragments as large as 1 Mb. Such vectors are maintained in yeast cells as artificial chromosomes (YACs). YAC methodology drastically reduces the number of clones to

be ordered; many YACs span entire human genes. A more detailed map of a large YAC insert can be produced by subcloning, a process in which fragments of the original insert are cloned into smaller insert vectors. YAC cloning was widespread, and many laboratories used this technique to obtain large cloned DNA fragments from different eukaryotic genomes.

One of the most widely used YAC vectors was pYAC4 (Figure 1.2-2), and it has the main features of the YAC vectors. This vector can replicate in *E. coli* and in yeast (*S. cerevisiae*). It consists of five important genetic elements inserted into *E. coli* pBR322-like plasmid:

1. Centromeric *CEN4* sequences required for centromere function.
2. Autonomous replicating sequences *ARS1* that are necessary for replication in yeast.
3. Telomere sequences from *Tetrahymena* ribosomal DNA (rDNA) that seed the formation of functional telomeres at high efficiency.
4. Selective marker for cloning, *SUP4* (*ochre*-suppressing allele of tyrosine tRNA gene). As cloning EcoRI and SmaI sites are located inside *SUP4*, insertion of any large DNA fragment into the cloning sites will inactivate *ochre* suppression function.
5. Two yeast selectable markers: wild-type genes *TRP1* and *URA3*, which are located on opposite sides of the cloning sites.

The yeast *HIS3* gene is just a stuffer fragment to separate two arms. The general scheme of the library construction is as follows (Figure 1.2-4).

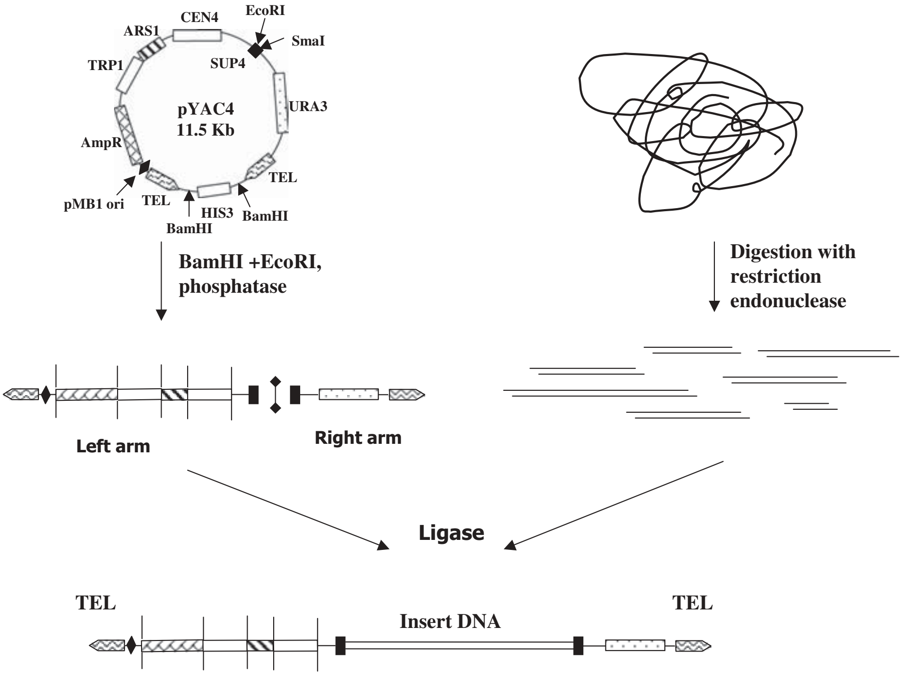

Figure 1.2-4. Construction of genomic library in YAC vectors. See text for more details.

The pYAC4 DNA is double digested with BamHI and SmaI (or EcoRI) to generate three fragments: left chromosomal arm containing *TEL*, *TRP1*, *ARS1*, and *CEN4* and right chromosomal arm with *TEL* and *URA3*. *HIS3* gene is discarded during the cloning procedure. The two arms are treated with alkaline phosphatase to prevent self-ligation and ligated with genomic DNA (usually) partially digested. The ligation product is transformed into yeast and selected for complementation of a mutated *ura3* gene present in yeast strain by the *URA3* gene in the vector. The grown transformants are selected for complementation of a host *trp1* mutated gene by the wild-type *TRP1* gene from the vector.

This double selection is necessary to ensure the presence in a recombinant YAC of both left and right arms and inactivation of the *SUP4* gene. *SUP4* is an especially useful cloning marker because in an *ade2-ochre* host, the cells with the functional *SUP4* gene are white and those in which the suppressor was inactivated form red colonies.

Using YAC vectors, several important genes were identified and cloned, e.g., *VHL*, *CDPX1*, *GART, and SON* [21–23]. Moreover, the first physical map covering the whole human genome was constructed with YAC contigs [24].

Although YACs greatly contributed to the progress in long-range mapping of the human genome, the construction of YAC contigs is not free from problems—certain regions of the human genome are difficult to clone in YACs. Moreover, repeat rich human sequences cloned in YACs are frequently unstable in yeast. Low transformation efficiency, the presence of an abundance of chimeric clones in nearly all YAC libraries, insert instability, and difficulties in DNA manipulation relative to bacterial systems are other important limitations.

Efforts to overcome the limitations of cosmids and YACs resulted in alternative large-insert cloning approaches using bacteriophage P1-based vectors and vectors based on the *E. coli* fertility plasmid (F-factor).

1.2.4.3 Bacterial (BAC) and P1-derived (PAC) Artificial Chromosome Vectors

BACs represent the state-of-the-art technology for such large-insert DNA library development. It has been demonstrated that BAC libraries are invaluable and desirable genetic resources for all kinds of modern structural, functional, and evolutionary genomics research. Genome-wide, as well as regional, physical maps of the human genome from BACs have been developed in different laboratories.

The BAC system is based on the well-studied *E. coli* F factor. Replication of the F factor in *E. coli* is strictly controlled. The F plasmid is maintained in low copy number (one or two copies per cell), thus reducing the potential for recombination between DNA fragments carried by the plasmid. Furthermore, F factors carrying inserted bacterial DNA are capable of maintaining fragments as large as 1 megabase pair, suggesting that the F factor is suitable for cloning of large DNA fragments. Individual clones of human DNA seem to be maintained with a high degree of structural stability in the host, even after 100 generations of serial growth.

The F factor not only codes for genes that are essential to regulate its own replication but also controls its copy number. The regulatory genes include *oriS*, *repE*, *parA*, and *parB*. The *oriS* and *repE* genes mediate the unidirectional replication of the F factor, whereas *parA* and *parB* maintain a copy number at a level of one or

two per *E. coli* genome. The BAC vector (pBAC108L) incorporates these essential genes as well as a chloramphenicol resistance marker and a cloning segment (Figure 1.2-2). The cloning segment includes (1) the bacteriophage lambda cosN and phage P1 loxP sites, (2) two cloning sites (HindIII and BamHI), and (3) several CG-rich restriction enzyme sites (Not I, Eag I, Xma I, Sma I, Bgl I, and Sfi I) for potential excision of the inserts. The cloning site is flanked by T7 and SP6 promoters for generating RNA probes for chromosome walking and for DNA sequencing of the inserted segment at the vector–insert junction. The cosN site provides a fixed position for specific cleavage with the bacteriophage lambda terminase. The loxP site can be used similarly. In this case, P1 Cre protein catalyzes the cleavage reaction in the presence of the loxP oligonucleotide. These sites (cosN and loxP) allow convenient generation of ends that can be used for restriction-site mapping to arrange the clones in an ordered array. Restriction maps of the individual clones can be determined by indirect end-labeling and subsequent partial digestion.

PAC vectors combine the best features of the P1 and BAC systems. One of the most commonly used PAC vectors is pCYPAC2 (Figure 1.2-2) that was constructed for the cloning of large DNA fragments using electroporation. Previously developed P1-based vectors (like pAd10SacBII) employed bacteriophages P1 or T4 *in vitro* packaging systems, enabling the cloning of recombinants with inserts in the 70–120-kb range.

The pCYPAC2 vector was constructed by removing the stuffer fragment from the pAd10SacBII vector and by inserting a pUC19 plasmid into the BamHI cloning site. During the cloning process, the pUC19 sequences are removed through a double-digestion scheme using BamHI and ScaI. Religation of the pUC19 and producing of nonrecombinant clones is prevented at three levels, as follows:

1. pUC19 is cleaved into two ScaI fragments. ScaI sticky ends are not compatible with BamHI.
2. Oligonucleotides BamHI–ScaI connecting vector sequences with the stuffer fragment are physically removed from the vector and stuffer fragments.
3. pCYPAC2 fragments are treated with alkaline phosphatase to inhibit self-ligation.

NotI sites are flanking inserts that make it possible to obtain an insert that is fragment free from the vector sequences.

Different modifications of original BAC and PAC vectors were constructed, e.g., capable of replicating in human cells too [25]. These vectors, e.g., pPAC4 (Figure 1.2-2) and pBACe4, facilitate the use of large-insert bacterial clones for functional analysis and contain two additional genetic elements that enable stable maintenance of the clones in mammalian cells:

(1) The Epstein–Barr virus replicon, *oriP*. It was included to ensure stable episomal propagation of the large insert clones upon transfection into mammalian cells.
(2) The blasticidin deaminase gene is placed in a eukaryotic expression cassette to enable selection for the desired mammalian clones by using the nucleoside antibiotic blasticidin.

Sequences important to select for loxP-specific genome targeting in mammalian chromosomes were also inserted into the vectors. In addition, the attTn7 sequence present on the vectors permits specific addition of selected features to the library clones. Unique sites have also been included in the vector to enable linearization of the large-insert clones, e.g., for optical mapping studies. The pPAC4 vector has been used to generate libraries from the human, mouse, and rat genomes.

Libraries constructed in lambda-based, BAC, and PAC vectors are widely used now in different laboratories, and almost nobody is currently working with libraries constructed in YAC vectors.

1.2.5 MAPPING OF THE HUMAN GENOME

As mentioned in the Introduction, mapping of the human genome was a major step in achieving the complete human genome sequence. Human genome maps were also important by themselves because they led to the isolation of many disease genes.

The 3 billion bp in the human genome are organized into 24 distinct, physically separate microscopic units called chromosomes. All genes are arranged linearly along the chromosomes. The nucleus of most human cells contains two sets of chromosomes, one set given by each parent. Each set has 23 single chromosomes—22 autosomes and an X or Y sex chromosome. A normal female will have a pair of X chromosomes; a male will have an X and Y pair. Chromosomes contain roughly equal parts of protein and DNA, and chromosomal DNA contains on average 150 million bases.

In general, all maps can be divided in two main classes: genetic and physical [see Refs. 3 and 4]. The genetic map is based on the frequency of recombination between two genetic markers on the chromosome. In fact, such a map just shows how these two markers are “linked” in respect to the frequency of recombination. Physical maps are based on physical distances between markers. Recombination frequencies define a genetic distance that is not the same as a physical distance. Two loci that show 1% recombination are defined as being 1 centimorgan (cM) apart on a genetic map. However, for distances above about 5 cM, human genetic map distances are not simple statements of the recombination fraction between pairs of loci. Loci that are 40 cM apart will show less than 40% recombination. This result reflects that recombination fractions never exceed 50% no matter how far apart are the loci. The female genetic map is larger than male due to a larger frequency of recombination. In general, for the whole human genome, the sex-averaged figure is 1 cM = 0.9 Mb, but the actual correspondence varies very significantly in different chromosomal regions. Usually there are more recombinations toward the telomeres of chromosomes and less toward the centromeres.

The value of the genetic map is that an the inherited disease can be located to the particular chromosomal region exploiting the inheritance of a DNA marker present in affected individuals (but absent in unaffected individuals), even though the molecular basis of the disease may not yet be understood nor the responsible gene identified. Genetic maps have been used to find the exact chromosomal location of several important disease genes, including cystic fibrosis, sickle cell disease, Tay-Sachs disease, fragile X syndrome, and myotonic dystrophy. Currently, some

genetic linkage maps contain more than 100,000 polymorphic markers (see, for example, http://www.ncbi.nlm.nih.gov/SNP/).

Different types of physical maps are based on different techniques. For instance, the cytogenetic map is based on detection chromosomal bands, and an average band has from one to several Megabase of DNA. Chromosomal breakpoint maps can be based on somatic cell hybrid panels containing human chromosome fragments derived from natural translocation or deletion chromosomes. The resolution for such maps is usually several Megabases. Monochromosomal radiation hybrid (RH) maps have a distance between breakpoints that is often several Megabases long. Whole genome RH maps have much higher resolution and can be as high as 0.5 Mb. The RH maps were very important for joining genetic and physical maps. They are based on *in vitro* radiation-induced chromosome fragmentation and cell fusion (merging human with other cells from other species to form hybrid cells) to create panels of cells with specific and varied human chromosomal components. Assessing the frequency of marker sites remaining together after radiation-induced DNA fragmentation can establish the order and distance between the markers.

Very useful were clone contig maps that could be constructed with YAC (or BAC, PAC) clones, and in this case, the average DNA insert has several hundred kilobases of DNA [24, 26]. If such a clone contig map was created using overlapping cosmid clones (average insert is 40–45 kb), the quality of such a map is significantly higher. A restriction map created with rare-cutting restriction enzymes like NotI can be very useful to check RH or clone contig maps [27].

A sequence-tagged site (STS) map requires prior sequence information and is based on mapping short known sequences using PCR amplification.

An expressed sequence tag (EST) map is based on STSs that were generated from cDNA.

DNA fragments are called DNA markers after they were mapped to particular chromosomal regions. Such DNA markers are prerequisites for physical and genetic mapping of the genome. DNA markers are also important in the diagnosis of genetic diseases. DNA markers can be divided into several different classes depending on the way in which the markers were selected among the fragments of genomic DNA. Examples of such classes are anonymous, micro- and minisatellites, restriction fragment length polymorphism (RFLP) markers, *NotI* linking clones, ESTs, STSs, and so on.

Another strategy of mapping is based on the completely different principle of NotI jumping and linking libraries [28, 29].

A big advantage to using chromosome jumping and linking clones is that they are small-insert vectors and mapping with these clones can be completely automated.

The basic principle of jumping is to clone only the ends of large DNA fragments rather than a continuous DNA segment (Figure 1.2-5). The DNA between two ends is deleted with the different biochemical techniques, and clones containing only the ends of a large DNA molecule are enriched by the mean of genetic or biochemical selection.

In general, jumping clones contain DNA sequences adjacent to neighboring NotI restriction sites, and linking clones contain DNA sequences surrounding the same NotI restriction site.

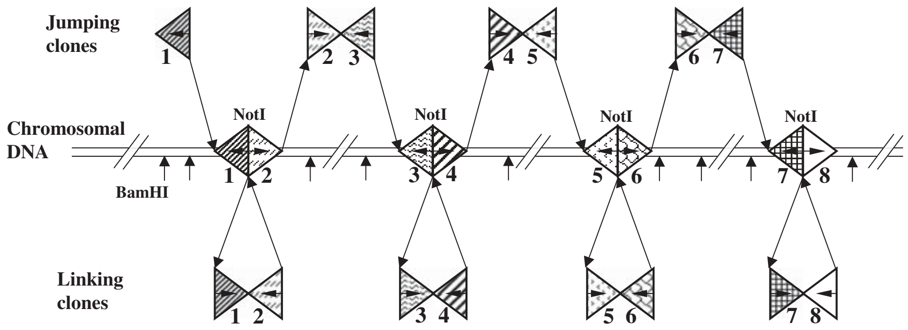

Figure 1.2-5. General scheme of long-range mapping using jumping and linking libraries. Small vertical arrows designate BamHI, and horizontal arrowheads show short sequences flanking NotI sites. Triangles indicate NotI–BamHI boundary fragments. See text for details.

A NotI jumping library is a collection of cloned DNA fragments that contains the ends of large NotI genomic DNA fragments. A NotI linking library is a collection of cloned genomic DNA fragments flanking the same NotI site. Basically, a linking library in combination with pulsed field gel electrophoresis (PFGE) is sufficient to construct a physical chromosomal map. When linking clones are used to probe a PFGE genomic blot, each clone should reveal two DNA fragments, and they must be adjacent in the genome. In principle, with just a single library and digest, one should be able to order the rare cutting sites, but in reality, it is not possible because many fragments could have the same size. Using these two types of libraries, it is possible to move fast along the chromosome because the human genome contains a limited number of recognition sites for this enzyme (10,000–15,000). The easiest way to establish the order of NotI sites is a shotgun sequencing of NotI linking and jumping clones (see below and Figure 1.2-5).

The most well-known and efficient way (integrated approach) to construct NotI linking and jumping libraries is shown in Figure 1.2-6 [30, 31].

To construct linking libraries (Figure 1.2-6B), genomic DNA is completely digested with BamHI. (Libraries can also be constructed with BglII, EcoRI, etc., but not with frequently cutting enzymes like MboI or infrequently cutting enzymes like SalI.) Subsequently, the DNA is self-ligated at a low concentration of DNA (without a *supF* marker), to yield circular molecules as the main product. To eliminate any remaining linear molecules, the sticky ends are partly filled-in with the Klenow fragment in the presence of dATP and dGTP (this is for the genomic DNA digested with BamHI; for other enzymes, partial filling-in with other nucleotides should be used). This way, all BamHI sticky ends will be neutralized and nearly all ends originated from linear molecules will be unavailable for ligation. Resulting DNA fragments are digested with NotI and cloned into λSK4, λSK17, and λSK22 vectors. These vectors permit the cloning of DNA fragments from 0.2 to 24 kb. The resulting phage particles are used to infect *E. coli* cells in which only recombinant phages could grow (spi- selection, [12]).

To construct the NotI jumping library, the same DNA and vectors can be used. However, the first steps are different. High-molecular-weight DNA is digested with

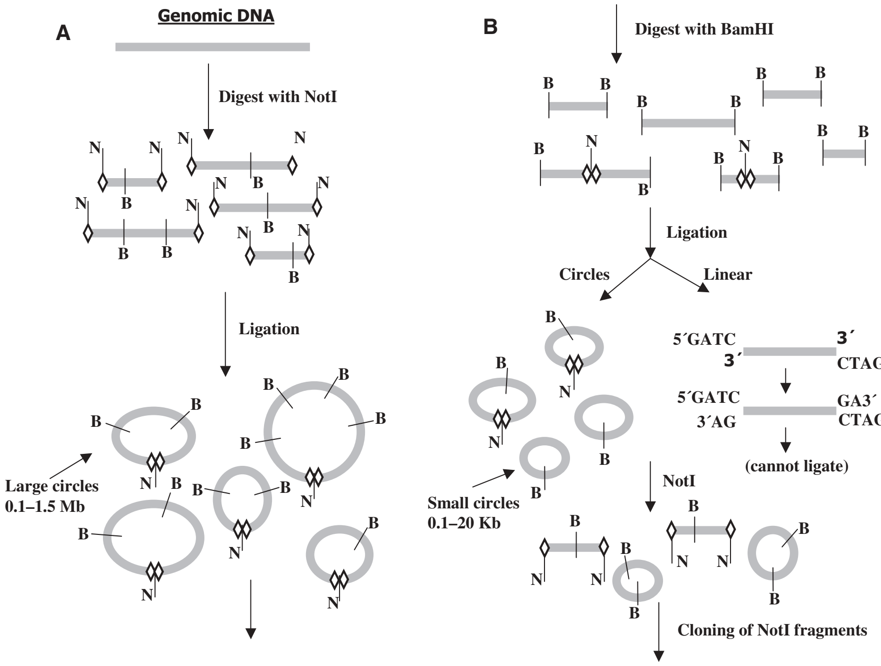

Figure 1.2-6. Construction of jumping (a and b) and linking libraries (b). B represents BamHI, and N denotes NotI sites. Digestion of genomic DNA with BamHI is a first step in construction of a linking library.

NotI and circularized at very low DNA concentration (0.1 µg/µL). Other steps were the same (Figure 1.2-6A).

The libraries can be converted into plasmid form, and sequences flanking NotI sites can be generated with standard sequencing primers. This sequence information can be used for generation of sequence tagged sites (STS). It was also demonstrated that the sequencing of these clones is a very efficient method for gene isolation because even short nucleotide sequences (approximately 500 bp from each side) flanking NotI sites are sufficient to detect genes [32, 33]. This approach was used for isolation of numerous new genes. The reason for this linkage of NotI sites and genes is the localization of practically all NotI sites in the CpG islands, which are tightly associated with genes.

A shotgun sequencing approach useful for the whole genome mapping was proposed for NotI linking and jumping libraries constructed in λSK17 and λSK22 vectors using an integrated approach [14, 29, 34]. This strategy was based on the fact that NotI sites in both libraries were available for the sequencing with standard sequencing primers, and sequence information about 800–1000 bp surrounding each NotI site could be easily obtained by automated sequencing. Plasmid DNA could be isolated automatically, and thousands of clones could be sequenced. Subsequently the linear order of the NotI clones can be established using a computer program. This approach is schematically illustrated in Figure 1.2-5.

NotI linking and jumping libraries were very important for the mapping of two regions in the short arm of chromosome 3 and isolation of tumor suppressor genes from the AP20 and LUCA regions (*RASSF1*, *G21*, *SEMA4B*, *RBSP3*, etc.).

1.2.6 MAIN APPROACHES TO SEQUENCE HUMAN GENOME

1.2.6.1 Hierarchical and the Whole Genome Shotgun Sequencing Scheme (WGS)

The international public (HGP) and American private (Celera) efforts to determine the sequence of the human genome exploited different approaches [9, 10, 35]. It is still not clear whether Celera's whole genome shotgun sequencing (WGC) approach was really efficient as they used publicly available data and it is not known to what extent.

The major points in the hierarchical or HGP approach [9] (Figure 1.2-7A) are as follows:

1. To construct a precise high-density STS map of the human genome. This map was integral and included not only STS but also genetic, microsatellite, FISH, and all other available mapping information.
2. To construct the clone contig of overlapping BAC and PAC clones. This contig was created and checked using a map constructed at the first step.
3. Each BAC or PAC clone was sequenced using a shotgun sequencing strategy. These sequences were assembled into the draft human genome sequence.

The shotgun sequencing approach for sequencing relatively small inserts was developed a long time ago [3, 4]. This method is based on the building of a complete

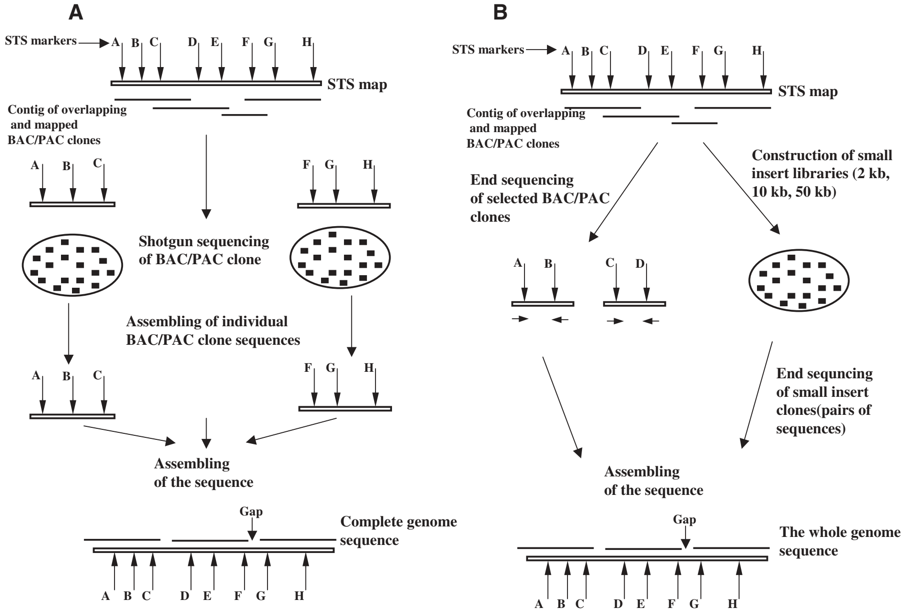

Figure 1.2-7. Two main approaches used to sequence the human genome. The hierarchical approach is based on creation of clone contigs covering the whole genome and shotgun sequencing of individual cosmid/BAC/PAC clones (a). The whole genome shotgun sequencing scheme (WGS) shown in (b) is based on pair-end sequencing of small-insert and selected BAC/PAC clones. See text for details.

insert sequence by randomly sequencing clones with overlapping inserts. To do this the insert DNA is subjected to partial digestion with a 4-bp cutter (like MboI) and the partially overlapping fragments are cloned at random into a suitable M13 or plasmid vector and sequenced. The sequence data obtained are fed into a computer programmed to detect overlaps between sequences and to assemble a composite sequence. Inevitably, this means a waste of efforts: The same sequence will be obtained over and over again.

Celera used a variant of this strategy that it named WGS [10] (Figure 1.2-7B). Central to the WGS strategy is preparation of high-quality plasmid libraries in a variety of insert sizes so that pairs of sequence reads (mates) are obtained; one is read from both ends of each plasmid insert. High-quality libraries have an equal representation of all parts of the genome and are constructed in three different sizes: 2 kb, 10 kb, and 50 kb. The method also involved end sequencing of some PAC clones that were carefully mapped. DNA fragments in these small-insert clones were generated by physical shearing of whole genomic DNA. According to the original predictions, this method requires the generation of sequences covering the whole genome not more than seven times.

The HGP and Celera announced that they have obtained a sequence of 92–97% of the human genome sequence and that a 7–10-fold genome sequence coverage is enough to generate an almost complete sequence for any human or mammalian genome. After 5 years, the scientific community understood that these estimations were overstated (see below), and even now when more than 10-fold genome sequence coverage was achieved, the human genome sequence is far from being complete.

An important point of both approaches is that the genome should be covered by sequences at least 10 times to yield contigs covering a significant part of the genome. If the coverage is not extensive enough, then sequences and clones will represent unconnected and unordered islands. Thus, despite impressive progress, mapping and sequencing even of small genomes, like from one bacterial strain, is still expensive and laborious. As a result, genome mapping and sequencing efforts need to be concentrated to big centers, and independent work by smaller groups is seriously hampered.

Partly in view of these logistic and economic limitations, HGP and Celera approaches may not be the optimal solution, especially for several experiments addressing biocomplexity. After completion of one sequence from an organism, in many cases there will be a great demand for comparison with other individuals, related species, pathogenic and nonpathogenic strains, and so on, in the growing field of comparative genomics. Such comparisons will be highly relevant for the better understanding of health, evolution, and ecology questions but must be performed by laboratories receiving considerably less funding than those involved in the recent high-profile sequencing efforts. Another area is a sequencing of related bacterial strains and species in order to identify the genomic basis of their biological differences and their interactions within the human intestinal flora. What is a difference between pathogenic and nonpathogenic members of the gut flora?

The whole genome sequencing will be performed only for the selected organisms. However, analysis of disease genes in other species may be extremely useful for the understanding of fundamental processes, leading to development of disease.

As the body of knowledge concerning the genome structure and genes in different organisms grows, it also becomes unnecessary to collect total sequences with 10–15-fold coverage for all organisms that would be interesting to study.

One of the most perspective solutions for this problem is sequencing using microarrays [36]. However, this approach will be not discussed here as it cannot be a strategy for the *de novo* sequencing. Two other alternative approaches that could be used for both the *de novo* and the comparative sequencing will be described below.

1.2.6.2 Massively Parallel Sequencing Approaches

The first publication using beads for massively parallel sequencing was published by Dr. Sydney Brenner et al. (2000) [37]. They described a novel sequencing approach that combined non-gel-based signature sequencing with *in vitro* cloning of millions of templates on separate 5-µM-diameter microbeads. After constructing a microbead library of DNA templates by *in vitro* cloning, a planar array of a million template-containing microbeads in a flow cell at a density greater than 3×10^6 microbeads/cm^2 was assembled. Sequences of the free ends of the cloned templates on each microbead were then simultaneously analyzed using a fluorescence-based signature sequencing method that does not require DNA fragment separation. Signature sequences of 16–20 bases were obtained by repeated cycles of enzymatic cleavage with a type IIs restriction endonuclease (BbvI), adaptor ligation, and sequence interrogation by encoded hybridization probes. The approach was validated by sequencing over 269,000 signatures from two cDNA libraries constructed from a fully sequenced strain of *S. cerevisiae*, and by measuring gene expression levels in the human cell line THP-1. This method is complicated and expensive and was used mainly for generation of SAGE tags (see below).

Recently MPSS principles were applied for long-range sequencing. Dr. George Church and his colleagues introduced a sequencer that uses a microscope and other off-the-shelf equipment [38]. With this technology, his team sequenced a strain of *E. coli* and could detect single-base-pair changes from an almost identical *E. coli* genome. The approach reduces sequencing costs by 90%. Dr. Jonathan Rothberg has demonstrated the power of another cost-cutting technology called “454” [39]. Using this approach, *Mycoplasma genitalium* was sequenced.

Both groups save money by eliminating the need for bacteria and miniaturizing the process wherever possible. Instead of bacteria, they attach DNA to aqueous beads encased in oil where PCR amplification was performed to produce the necessary amount of DNA. That change alone could reduce by two thirds the costs associated with space and personnel. Moreover, both perform many thousands of these sequencing reactions at once in miniature “reactors,” decreasing the need for expensive chemicals. Once the DNA is ready, the two technologies diverge: The “454” technique uses pyrosequencing [40] to identify the bases and Church’s technique (MPS, multiplex polony sequencing) uses bursts of different fluorescent colors, one each to a particular base, to distinguish the bases (sequencing by ligation, [41]). Both use high-speed charge-coupled device cameras to record the labeled bases.

The “454” technique uses a novel fiber-optic slide of individual wells and can sequence 25 million bases, at 99% or better accuracy, in one 4-hour run. To achieve

an approximately 100-fold increase in throughput over current Sanger sequencing technology, an emulsion method for DNA amplification and an instrument for sequencing by synthesis using a pyrosequencing protocol optimized for solid support and picolitre-scale volumes was developed. In a pilot experiment, 96% of the *M. genitalium* genome was covered by sequence contigs at 99.96% accuracy in one run of the machine. The method could potentially allow one individual to prepare and sequence an entire genome in a few days. The sequencer itself, equipped with a simple detection device and liquid delivery system, and housed in a casing roughly the size of a microwave oven, is actually relatively low-tech. The complexity of the system lies primarily in the sample preparation and in the microfabricated, massively parallel platform, which contains 1.6 million picoliter-sized reactors in a 6.4-cm^2 slide.

Sample preparation starts with fragmentation of the genomic DNA, followed by the attachment of adaptor sequences to the ends of the DNA pieces. The adaptors allow the DNA fragments to bind to tiny beads (around 28 μm in diameter). This is done under conditions that allow only one piece of DNA to bind to each bead. The beads are encased in droplets of oil that contain all reagents needed to amplify the DNA using a standard tool called the PCR. The oil droplets form part of an emulsion so that each bead is kept apart from its neighbor, ensuring the amplification is uncontaminated. Each bead ends up with roughly 10 million copies of its initial DNA fragment.

To perform the sequencing reaction, the DNA-template-carrying beads are loaded into the picoliter reactor wells—each well having space for just one bead. The technique uses a sequencing-by-synthesis method developed by Dr. Uhlen and colleagues [40], in which DNA complementary to each template strand is synthesized. The nucleotide bases used for sequencing release a chemical group as the base forms a bond with the growing DNA chain, and this group drives a light-emitting reaction in the presence of specific enzymes and luciferin. Sequential washes of each of the four possible nucleotides are run over the plate, and a detector senses which of the wells emit light with each wash to determine the sequence of the growing strand.

This new system shows great promise in several sequencing applications, including resequencing and *de novo* sequencing of smaller bacterial and viral genomes. It could potentially allow research groups with limited resources to enter the field of large-scale DNA sequencing and genomic research, as it provides a technology that is inexpensive and easy to implement and maintain. However, this technology cannot yet replace the Sanger sequencing approach for some of the more demanding applications, such as sequencing a mammalian genome, as it has several limitations [42].

First, the technique can only read comparatively short lengths of DNA, averaging 80–120 bases per read, which is approximately a tenth of the read-lengths possible using Sanger sequencing. This means not only that more reads must be done to cover the same sequence, but also that assembling short reads into longer genomic sequences is a lot more complicated. This is particularly true when dealing with genomes containing long repetitive sequences.

Second, the accuracy of each read is not as good as with Sanger sequencing—particularly in genomic regions in which single bases are constantly repeated. Third, because the DNA "library" is currently prepared in a single-stranded format,

unlike the double-stranded inserts of DNA libraries used for Sanger sequencing, the technique cannot generate paired-end reads for each DNA fragment. The paired-end information is crucial for assembling and orientating the individual sequence reads into a complete genomic map for *de novo* sequencing applications.

Finally, the sample preparation and amplification processes are still complex and will require automation and/or simplification.

In the MPS technique, sheared, size-selected genomic fragments (approximately 1 kb in size) were circularised with a linker bearing MmeI (type IIs restriction enzyme) recognition site (TCCRAC). Then all noncircularized material was destroyed with exonuclease and circular molecules were amplified using rolling circle amplification with random hexamers. Afterward, resulting material was digested with MmeI. MmeI digests at a distance of 18/20 or 19/21 from its recognition site. In the MPS protocol, MmeI digestion results in 17-bp or 18-bp tags of unique genomic sequence. A sharp band at approximately 70 bp was purified with 6% PAGE, and DNA ends were blunted and ligated to two adaptors of different lengths. The molecules with two different adaptors at their ends were again purified using 6% PAGE and PCR amplified. Then sharp bands at approximately 135 bp were purified on a 6% PAGE gel and emulsion PCR with 1-μm magnetic beads containing biotin labeled primer was performed. Millions of beads with amplified DNA fragments (paired tags) were immobilized in acrylamid-based gel system and a four-color sequencing by ligation was made [41]. This method allowed to obtain 13-bp sequencing information per tag separated by a 4- to 5-bp gap (sequencing per each tag was done from both ends). Thus, 26-bp information per amplicon was obtained (2 tags × 13 bp). In a pilot experiment, this technology was applied to resequence an evolved strain of *E. coli*, and according to the estimation, this was done on less than a one-error-per-million consensus bases. In this pilot experiment, two deletion genomic fragments and several 1-bp substitutions were detected in the analyzed *E. coli* strain.

Still, neither "454" nor the MPS method is up to speed yet. The accuracy of both should be improved by at least one order of magnitude. Also, to sequence mammalian genomes the length of sequence generated should be about 700 bases, but reads reported from these new approaches are between 26 and 110 bases.

1.2.6.3 Slalom Library: A Novel Approach to Genome Mapping and Sequencing

All described above sequencing approaches were based on sequencing of randomly generated DNA fragments.

We recently suggested a completely different and efficient strategy for simultaneous genome mapping and sequencing. The approach was based on physically oriented, overlapping restriction fragment libraries called slalom libraries. Slalom libraries combined features of general genomic, jumping, and linking libraries. Slalom libraries could be adapted to different applications, and two main types of slalom libraries will be discussed below. This approach was used to map and sequence (with ~46% coverage) two human PAC clones, each of ~100 kb. This model experiment demonstrates the feasibility of the approach and shows that the efficiency (cost-effectiveness and speed) of existing mapping/sequencing methods

could be improved at least 5–10-fold. Furthermore, as the efficiency of contig assembly in the slalom approach is virtually independent of length of sequence reads, even short sequences of 19–20 bp produced by rapid, high-throughput sequencing techniques would suffice to complete a physical map and a sequence scan of a small genome.

Two slalom libraries are used in the first type of approach. This approach allows us to construct contigs of plasmid clones covering a whole genome. However, these contigs will contain some gaps. Comparatively modest sequence information can be generated (20–25% of a genome). Using this technique, two (or more) bacterial strains (e.g., pathogenic and nonpathogenic) could be quickly compared and pathogenic islands could be identified.

The main principle of the type I slalom libraries is shown in Figure 1.2-8 and looks similar to the computer-assisted long-range mapping with NotI linking and jumping clones (Figure 1.2-5). In this case, the role of NotI jumping library plays a standard EcoRI genomic (slalom "R") library that is produced by complete digestion of genomic DNA with EcoRI, and the role of a NotI linking library–EcoRI linking (slalom "BR") library. Slalom "BR" library is constructed in exactly the same way as a NotI linking library using BamHI as a second enzyme and fulfills the connecting function joining EcoRI fragments. Shortly, DNA is digested with BamHI, circularized and cut with EcoRI ("BR" library). Thus, EcoRI in this case plays the role of a NotI enzyme.

Sequences from "BR" and "R" libraries are produced using standard reverse and forward sequencing primers and overlapping clones are found using a computer program. The homologies found will join the ends of EcoRI fragments in the "BR" library with the ends of EcoRI fragments in the "R" library to yield an ordered set of BamHI–EcoRI clones/STSs distributed along the genome.

Figure 1.2-8 shows the scheme where EcoRI and BamHI sites alternate. In reality, EcoRI sites and BamHI sites do not always alternate, and this will lead

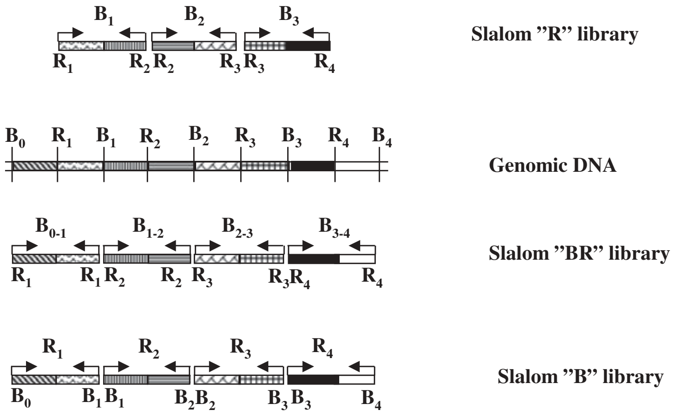

Figure 1.2-8. The main idea of the slalom approach. Numbers designate identical end sequences in different libraries that can be joined by a computer program in a contig of overlapping clones. B represents BamHI, and R denotes EcoRI sites. Small horizontal arrows show short sequences flanking EcoRI sites. The "BR" library plays a role of a linking library where EcoRI replaces NotI. The ordinary "R" library plays the role of a jumping library where EcoRI replaces NotI.

to the gaps in this set of overlapping clones, if several EcoRI or BamHI sites lie together. Thus, the genome will not be completely covered by clones because the information between some EcoRI and BamHI sites will be missing.

The problem with the gaps can be solved using the second variant of the slalom libraries (type II) where three libraries are used:

1. *Standard, completely EcoRI digested (slalom "R") library*
2. *Standard, completely BamHI digested (slalom "B") library*
3. *EcoRI jumping (slalom "RBR" or connecting) library*

This approach results in generation of plasmid clone contigs covering a whole genome without gaps. A large volume of sequencing information can be obtained (45–55% of a genome). The connecting library in this case is similar to a NotI jumping library. If the ultimate aim is to sequence the complete genome, then sequencing gaps could be filled-in using standard methods such as primer walking or transposon-mediated sequencing.

An "RBR" slalom library or EcoRI jumping library is prepared in the same way as a NotI jumping library using as a second enzyme BamHI. The only difference is that circularization after BamHI digestion is performed in the presence of a selective marker (e.g., Kan^R gene or oligonucleotide adaptor, etc.). The circular constructs are opened with EcoRI and cloned [43].

The "RBR" library can be constructed in a simpler way. Plasmid DNA isolated *en masse* from a slalom "R" library is digested with BamHI and circularized in the presence of Kan^R. Then *E. coli* cells are transformed with ligated DNA and plated on agar with kanamycin. The clones obtained in this manner will be identical in structure to the clones from an EcoRI jumping library prepared using the classic method.

By comparing the end sequences of the "B" library clones with the internal BamHI (from the marker fragment) sequences of the slalom "RBR" library clones, the BamHI clones can be positioned in relation to each other. After the comparison of end sequences in "R" and "RBR" libraries, EcoRI clones will be positioned relative to each other. Finally, EcoRI and BamHI clones will be assembled into a contig representing their organization in complete genome.

The EcoRI jumping library provides the connecting function in type II slalom libraries.

The major difference between the slalom library mapping/sequencing approach and other sequencing strategies is that the clones are generated according to a specific scheme and using complete digestion. As a result, the number of variants required to cover the whole genome decreases significantly. The preparation of libraries for the slalom approach is remarkably simple: Only complete digestion with EcoRI or BamHI is used. There is no need for size separation, agarose gel purification, or establishing conditions for partial shearing/digestion. There is no need to develop a new sequenator as any existing instrument can be used. Importantly, it is not necessary to keep all slalom clones because sequencing information can be used to design PCR primers and even large fragments (up to 40–50 kb) can be amplified by long-range PCR.

The slalom library approach differs fundamentally from the shotgun sequencing approach with respect to the efficiency of assembly (EOA). The EOA for the latter method is strictly dependent on the length of sequencing reads. The longer the reads, the higher the EOA. As the slalom approach uses nonrandom fractionation of the DNA and each start site is tightly linked with the recognition site for the restriction enzyme, even very short sequences will, in principle, be enough to create a contig of the overlapping clones. The EOA of the slalom library approach is, therefore, essentially independent of read-length. Even the short sequences generated by pyrosequencing, MPS, or MPSS [37–40] should be sufficient to completely cover a genome. As one person can generate thousands of sequences a day using a pyrosequencer, the minimal set of overlapping clones covering a 4-Mb genome can be completed in a couple of days. Repeat sequences are in fact less of a problem for the slalom approach than for the shotgun sequencing approach for several reasons [43].

It is important to stress that the benefits of the slalom approach are most obvious in comparative sequencing experiments in combination with high-throughput techniques like pyrosequencing or MPSS (which are not compatible with the shotgun sequencing approach). Our particular experiments demonstrated that approximately 4% coverage would be enough to construct the contig of the overlapping clones and subsequently generate >20% ordered sequences with almost 100% efficiency, i.e., with 0.2-fold coverage.

Of course, closing of the gaps will be done with significantly lower efficiency. However, the finishing stages of the shotgun sequencing approach are also the most expensive and time-consuming part of the process. Lander et al. [9] distinguished three types of gaps: gaps within unfinished sequenced clones; and gaps between sequenced clone contigs, but within fingerprint clone contigs; and gaps between fingerprint clone contigs. The first type is the simplest, and the third is the most complicated to close because constructing a contig of overlapping clones is the most difficult procedure. With the slalom approach, we already have a contig of overlapping clones, and thus, we will only suffer from the first, simplest type of gaps. It is important to mention another difference in the finishing stages of these two approaches. With the shotgun sequencing approach, sequences from different clones must be connected, and here highly related repeats, gene families, and polymorphisms will represent a major problem. These problems are nonexistent in the slalom approach, where a single insert should be sequenced.

The slalom strategy can increase several orders of magnitude the efficiency of mapping and sequencing, i.e., decrease the cost and labor, and increase the speed of sequencing project fullfillment (see Table 1.2-1). This strategy will allow the establishment of a physical map with a minimal set of overlapping clones that will pinpoint differences in genome organization between organisms. At the same time, a considerable sequence coverage (about 50%) of the genome at a less than onefold coverage will be achieved. This will make it possible to locate virtually every gene in a genome for more detailed study. The method makes it economically and logistically possible for a wide range of laboratories to gather the detailed information about large numbers of genomes. It offers a way to use genomics techniques for the study of biocomplexity, evolution, and taxonomy in the close future.

TABLE 1.2-1. Slalom Strategy and Shotgun Sequencing Approach

	Slalom	Shotgun
Sequence coverage 1.2-fold	A. Minimal set of overlapping clones; restriction map B. 20–25% of sequences are ordered into STS islands covering the whole genome (+appr. 30% of unordered sequences)	A. Random clones, no map B. Practically no ordered sequences (appr. 50–70% of unordered sequences)
Pyrosequencing 4% coverage	Minimal set of overlapping clones; restriction map	No use
Pyrosequencing plus sequencing unique clones (25–30% coverage)	20–25% of sequences are ordered into STS islands covering the whole genome	No use
Sequence coverage needed to achieve 95% of complete sequence	1	10–15
Sequence coverage needed to compare two genomes and isolate clones/genes completely covering regions of divergence	4% (0.04-fold)	At least 6–8-fold (600%–800%)

1.2.7 IDENTIFICATION OF GENES. HOW MANY GENES ARE IN THE HUMAN GENOME?

1.2.7.1 Many Approaches Exist for Gene Identification

The most important for the majority of research tasks is identification of genes in a particular region of the human genome. The different tissues in the body express information across a wide range, between less than 2000 (in specialized and terminally differentiated white blood cells) and more than 20,000 (in the placenta). Several methods were suggested previously for gene identification [3, 4]. Genomic DNA can be used as a probe to screen cDNA libraries. Different approaches were developed to capture cDNA clones using genomic DNA attached to a solid substrate (e.g., magnetic beads, nylon filters) as a target to that cDNA clones can hybridize. To identify genomic sequences that could be expressed as a special approach, exon trapping was suggested. For example, in the method of Church et al. [44], the DNA is subcloned into a plasmid expression vector pSPL3 that contains an artificial minigene that can be expressed in a suitable host cell. The minigene consist of the following:

1) Segment of the simian virus 40 (SV40) genome that contains an origin of replication plus a powerful promoter sequence.

2) Two splicing-competent exons separated by an intron that contains a multiple cloning site (MCS).
3) SV40 polyadenylation site.

The recombinant DNA is transfected into a strain of monkey cells, known as COS cells. COS cells were derived from monkey CV-1 cells by artificial manipulation, leading to integration of a segment of the SV40 genome containing a defective origin of replication (*ori*). The integrated SV40 segment in COS cells allows any circular DNA that contains a functional *ori*SV40 to replicate independently of the cellular DNA. Transcription from the SV40 promoter results in an RNA transcript that normally splices to include the two exons of the minigene. If the DNA cloned into the MCS contains a functional exon, then the additional exons can be spliced to the minigene exons. After isolation of RNA and preparing cDNA, PCR reactions with primers specific for the minigene exons is made. Agarose gel electrophoresis can easily distinguish between normal splicing and splicing involving exons in the insert DNA.

Another method to identify expressed sequences is called zoo-blotting. In this method, genomic DNA fragments are hybridized at reduced hybridization stringency against a Southern blot of genomic DNA samples isolated from different species. This method is based on a fact that expressed sequences are usually well conserved, and for example, human DNA fragment with exons from *RB1* gene will hybridize to mouse and pig genomic DNA fragments containing *RB1* gene.

However, all of these methods are laborious, time consuming, and inefficient.

Currently, three approaches are the most popular for the identification of expressed sequences/genes in the genomic DNA: computer analysis of DNA sequences for possible exons, identification of CpG islands that can be done both experimentally and using bioinformatics, and large-scale sequence analysis of transcribed sequences, like sequencing of ESTs, SAGE, and CAGE.

Bioinformatic methods to identify genes will not be discussed here as special journal issues are focused on this topic, and many new programs appeared every year. In principle, these programs could be divided into two classes. One type of program predicts genes using only genomic sequences. These programs can also compare genomic DNA sequences from different organisms and search for conserved sequences. The second type of program compares different cDNA, EST, and genomic sequences to find the most possible gene sequence. This method is more reliable; however, it is important to remember that all computer programs frequently predict nonexisting genes and exons and miss really existing genes and exons. Thus, all computer-predicted genes/exons need experimental confirmation. In cases when a gene has alternative 5′ and 3′ ends and different splicing forms computer programs are not very much helpful.

1.2.7.2 CpG Islands

The dinucleotide CpG is notable because it is greatly under-represented in human DNA, occurring at only about one fifth of the roughly 4% frequency that would be expected by simply multiplying the typical fraction of Cs and Gs (0.21×0.21). The deficit occurs because most CpG dinucleotides are methylated on the cytosine base, and spontaneous deamination of methyl-C residues gives rise to T residues.

Spontaneous deamination of ordinary cytosine residues gives rise to uracil residues that are readily recognized and repaired by the cell. As a result, methyl-CpG dinucleotides steadily mutate to TpG dinucleotides. However, the genome contains many CpG islands that represent stretches of unmethylated DNA with a higher frequency of CpG dinucleotides when compared with the entire genome [9, 10, 13, 32, 33, 45]. CpG islands are believed to preferentially occur at the transcriptional start of genes, and it has been observed that most housekeeping genes have CpG islands at the 5′ end of the transcript. In addition, experimental evidence indicates that CpG island methylation is correlated with gene inactivation and has been shown to be important during gene imprinting and tissue-specific gene expression. Thus, identification of CpG methylation is crucial for isolation of tumor suppressor genes and early diagnosis of cancer [46, 47].

CpG islands are usually 1–2 kb long and are dispersed in the genome. They are called CpG (rich) islands because the %(G+C) of CpG island sequences usually exceed 60% and the human genome contains on average about 40% of C+G content. The combination of G+C richness and lack of CpG suppression means that CpG islands contain 10–20 times more CpGs than an equivalent length of non-island DNA. Altogether, there are about 30,000 to 45,000 islands in the haploid genome (the average spacing is about 1 per 100 kb). It is now clear that the majority (if not all) of CpG islands are associated with genes.

As one of the main goals of the human genome project is the isolation of all genes and the construction of a transcriptional gene map, it is clear that markers located in the CpG islands have an additional value for physical mapping. It has been shown that recognition sites for many of the rare cutting enzymes are closely associated with CpG islands. For example, at least 82% of all NotI and 76% of all XmaIII sites are located in the CpG islands. More than 20% of CpG island-containing genes have at least one NotI site in their sequence, whereas about 65% of those genes have XmaIII site(s). Summarizing the data for all genes (with or without CpG islands), we can conclude that approximately 12% of all well-characterized human genes contain NotI sites, and 43% of them have XmaIII sites. For human genome mapping this means that by sequencing DNA fragments containing a NotI site, it is possible to tag up to one fifth of all expressed genes. As discussed, the recombinant clone containing a NotI (or other rare cutting enzymes) recognition site is called a linking clone.

How many genes contain the human genome? This question is difficult, and the answer is very much dependent on the definition of a gene. According to Celera and HGP, the human genome contains approximately 30,000–35,000 genes.

However, sequencing of NotI linking clones suggested that the human genome contains 15,000–20,000 *Not*I sites, of which 6000–9000 are unmethylated in any particular cell. It means that the human genome contains 45,000–60,000 genes [33].

Comparison of our database containing experimentally obtained NotI linking sequences with complete chromosome 21 and 22 sequences revealed several interesting features. First, it was shown that chromosome 22 contains greater than twofold more genes than chromosome 21 (545:225 = 2.4), and we see the same ratio within the NotI flanking sequences (119:49 = 2.4). We have demonstrated that nearly all our NotI clones contained genes and suggested that 12.5–20% of all genes contain NotI sites [32]. This correlates well with the number of genes on

chromosomes 21 and 22 (168/770 = 22%). Second, according to sequencing, the two chromosomes contain 390 NotI sites. Therefore, if we assume that each NotI site is associated with a gene, then almost half of the genes contain NotI sites. This estimate seems excessive.

The human genome sequence data cannot discriminate between methylated and unmethylated cytosines. There are several algorithms for the identification of CpG islands on the basis of primary sequence. One quantitative definition holds that CpG islands are regions of DNA >200 bp with C+G content of >50% and a ratio of the "observed vs. expected" frequency of CG dinucleotides, which exceeds 0.6 [48, 49]. The ratio for the entire genome is approximately 0.2 [9]. According to the previous data, 82% of NotI sites are located in CpG islands (see above). It is important to note that these data were obtained either using computational methods or limited experimental datasets. Using the NotI cloning method, only unmethylated NotI sites can be isolated. Comparing the experimental NotI cloning method and computer-based identification of CpG islands [9, 33], two main features are apparent: The fraction of sequences with >80% CG content is nine times higher in the NotI collection, i.e., 142 vs. 22 sequences. Another striking finding is that even NotI flanking sequences with CG content less than 50% have a very high ratio of observed versus expected frequency of CG dinucleotide: 0.71. This suggests that essentially all NotI flanking sequences generated in the study are located in CpG islands, and therefore, the computational method misses at least 8.7% of CpG islands associated with NotI sites. Thus, existing tools for computational determination of CpG islands fail to identify a significant fraction of functional CpG islands, and unmethylated DNA stretches with a high frequency of CpG dinucleotides can be found even in regions with low CG content.

1.2.7.3 SAGE and CAGE Approaches to Analyze Human Transcriptome and to Estimate the Number of Human Genes

Another approach to identify genes and analyze their expression pattern in human/mammalian cell is large-scale sequencing of transcribed sequences. Sequencing of ESTs and isolation of full-length cDNA clones was known a long time ago and will not be discussed here. Recently two novel high-throughput methods for the analysis of human transcriptome were developed: serial analysis of gene expression (SAGE, [50]) and cap analysis gene expression (CAGE, [51]). Both methods are based on the generation of short sequence tags. Each of these tags is assumed to identify a gene transcript.

SAGE is based on two principles. First, a specific adaptor is ligated to cDNA close to the 3′ end of the mRNA (polyA tail). This adaptor contains a recognition site for a type IIs restriction aendonuclease. Originally, it was FokI, and in a recent modification (LongSAGE), MmeI was used [50, 52]. FokI generates 13–14-bp, and MmeI generates 20–21-bp tags. The 21-bp tag consists of a constant 4-bp sequence representing the restriction site at which the transcript was cleaved, followed by a unique 17-bp sequence derived from an adjacent sequence in each transcript. Theoretical calculations show that >99.8% of 21-bp tags are expected to occur only once in genomes the size of the human genome. Similar analyses based on actual sequence information from ~16,000 genes suggest that >75% of 21-bp tags would be expected to occur only once in the human genome, with the remaining tags

matching duplicated genes or repeated sequences. Second, to optimize the quantification of transcripts, tags are ligated together to form "ditags," which are then concatenated and cloned. Sequencing tag concatemers in parallel allows the identification of up to ~30 tag sequences in each sequencing reaction. Matching tags to genome sequences identifies the gene corresponding to each tag, and the number of times a particular tag is observed provides a quantitative measure of transcript abundance in the RNA population.

CAGE is similar to SAGE in principle; however, it is based on preparation and sequencing of concatamers of DNA tags deriving from the initial 20 nucleotides from 5′ end mRNAs.

The method essentially uses cap-trapper full-length cDNAs to the 5′ ends of which linkers are attached [53, 54]. This is followed by the cleavage of the first 20 base pairs by class IIs restriction enzymes (Mme) and then another linker is ligated. After it, PCR amplification, excision of tags, their concatamerization, and cloning of the CAGE tags was performed. CAGE tags derived by sequencing these clones are mapped to the genome and used for expression analysis, as well as for the determination of the 5′ end borders of new transcriptional units. Thus, in contrast to SAGE, CAGE allows high-throughout gene expression analysis and the profiling of transcriptional start points, including promoter usage analysis.

SAGE and CAGE concatamer sequencing is more cost-effective than a full-length cDNA library sequencing because of the much higher throughput of identified tags.

In a recent study (FANTOM 3 project), full-length cDNA isolation and 5′- and 3′-end sequencing of cloned cDNAs was combined with CAGE, gene identification signature (GIS), and gene signature cloning (GSC) ditag technologies for the identification of RNA and mRNA sequences corresponding to transcription initiation and termination sites [55]. In this study, paired initiation and termination sites were identified and the boundaries for 181,047 independent transcripts in the mouse genome were established. In total, 1.32 5′ start sites for each 3′ end and 1.83 3′ ends for each 5′ end are found. Based on these data, the number of transcripts is at least one order of magnitude larger than the estimated 22,000 "genes" in the mouse genome, and the large majority of transcriptional units have alternative promoters and polyadenylation sites. To extend the mouse data, two human CAGE libraries, one constructed with random primers and the other with oligo-dT primers, were combined to produce 1,000,000 CAGE tags. Mapping of these tags to the human genome identified the likely promoters and transcriptional starting site of many genes and clearly indicates that the same level of transcriptional diversity occurs in humans as in mice and is at least 10 times as great as the number of "genes."

Of the 102,281 FANTOM3 cDNAs, 34,030 lack any protein-coding sequence (CDS) and are annotated as non-protein-coding RNA (ncRNA). The function of ncRNAs is a matter of debate [56], but it is clear that some of them are very important for transcription regulation. Some ncRNAs are highly conserved even in distant species. According to the previous data, only 1–1.5% of the human genome is spanned by exons and 75% of the genome is non-transcribed intergenic DNA. However, FANTOM 3 data demonstrated that the majority (more than 60%) of the mammalian genome is transcribed and commonly from both strands.

Analysis of the output of FANTOM 3 suggested that many more transcripts were still to be discovered and only the future can reveal the actual complexity in

the mammalian transcriptome. Very similar conclusions were made in another detailed study of human transcriptome [57, 58].

1.2.8 WAS IT WORTH IT TO SEQUENCE HUMAN GENOME?

The Human Genome Project was controversial from the beginning. Some criticism concerns scientific strategy and the ways in which it was executed [1–4]. Is it important to sequence the whole human genome or only coding DNA sequences (genes)? Now it is clear that DNA sequences recognized previously as a "junk" in fact are very important for understanding how human genome functions. This "junk" DNA contains important regulatory sequences, ncRNAs, and probably the most intriguing discoveries will come from areas considered as wastelands. Many ethical questions arose during the HGP. For instance, sample collection from individuals was often done without proper consultation or explanation of the possible future use. As the HGP moved forward, commercial concerns were increasingly taking a stake in the research. Large financial investments from big companies can monopolize certain research areas, for example, sequencing of cDNA and gene identification. By subsequently seeking patents to protect their financial investments, they raised a question: Who owns the human genome?

Any major scientific advance carries with it the fear of exploitation, and HGP is not an exception. For example, knowledge of disease-associated mutations can be used for disease prevention, and at the same time, it can be used for discrimination. The comprehensive knowledge of human genome and genes can lead to biological determinism and revival of eugenics with all its negative consequences.

Another objection was that funding of the HGP would be done at the expense of other scientific directions.

The human genome map and sequence still contain many uncertainties, and only careful examination by some research group focusing on a particular genomic region can produce a reliable map and sequence. For instance, we have cloned all *Not*I sites and constructed a physical map for two chromosome 3 regions containing tumor suppressor genes [26, 59, 61]. In the course of these studies, it became apparent that large-insert vectors from these regions were unstable, sensitive to deletions and rearrangements, and the original maps produced by HGP were erroneous [26, 59, 60].

It should be emphasized that the enormous efforts deployed on sequencing the human genome are extremely important; however, a critical role remains for verified, integrated maps. In sequencing, the short and long repeats spread throughout the genome are sources of numerous errors. These errors are difficult to identify with the shotgun strategy, but they become evident when mapping information is combined with the sequence. Furthermore, difficulties in sequence assembly caused by the existence of large families of recently duplicated genes and pseudogenes are easier to resolve using integrated maps.

In many cases, sequence and mapping information is duplicated, overlapping, or contradictory. One must always keep in mind that even absolutely correct and long nucleotide sequences may be localized incorrectly along the chromosomal DNA if the appropriate accompanying mapping information is ignored. For this reason, despite the vast amount of information currently available, there is an

urgent need to reconcile this information in a unified framework, to generate an integrated noncontroversial map for each chromosome.

The draft human genome sequence produced by HGP was estimated to cover at least 92% of the whole human genome. However, it contained only 55.7% of the *Not*I flanking sequences and Celera's database contained matches to 57.2% of the clones. The data suggest that the shotgun sequencing approach used to generate the draft human genome sequence resulted in a bias against cloning and sequencing of *Not*I flanks. Even in 2005 up to 5% of our NotI flanking sequences (that are also incomplete!) are not present in the human genome sequence available in public databases.

Several explanations can be offered to account for the low representation of *Not*I flanking sequences in the draft human genome sequences. One potential explanation is that the cloning of some *Not*I containing regions may be selected against experiments with large-insert cloning vectors. Our experience has also proven that even in small-insert plasmid vectors, some human sequences are more easy to clone than other. In our procedure, we directly selected clones containing *Not*I sites, and in a shotgun sequencing approach, such sequences could be under-represented. An alternative explanation, based on the observation that some *Not*I flanking sequences can have 100% identity over long DNA stretches [62], is that some *Not*I sites were incorrectly fused in the assembly process. Furthermore, our experience demonstrated that sometimes it is very difficult to read *Not*I flanking sequences because of extremely high CG content. During human genome assembling, such sequences would be eliminated as possessing low-quality data. Further experimental analysis is needed to conclusively identify the cause(s) of the bias.

HGP resulted in enormous progress in automation of sequencing and other molecular biology methods.

It gives us new tools for disease-gene discovery. In fact, the information obtained during the HGP helps rather than hinders small research groups. It is still important to remember that only the euchromatin portion of the genome was sequenced, and it is not clear to what extent it was done. Many heterochromatin regions are practically not sequenced, and they most probably contain many unknown genes and other functionally important sequences. Thus, the draft human genome sequence was made, but it is a very long way to obtain a really complete human genome sequence and to understand how many genes it contains and how it functions.

ACKNOWLEDGEMENT

1.3.1 INTRODUCTION

The probability of success in drug discovery and development is highly dependent on good planning right from the beginning, a rational approach to each phase in the light of the ultimate goal, and—unsurprisingly—good science. There are many possible reasons for the recent dearth of new molecular entity or new biological entity submissions to regulatory agencies [1, 2]. One possible reason is suboptimal discovery and development strategies for novel targets with little known biology [3]. In the late 1980s and early 1990s, drug discovery was specialized to an extent, with small-molecule drug discovery the domain of pharmaceutical companies and macromolecule discovery practiced by biotechnology companies. Today, drug discovery in both areas is practiced widely in both arenas. Large pharmaceutical companies have embraced biological therapies, in particular therapeutic antibodies, and large biotechnology companies have added small-molecule discovery to complement their macromolecular portfolio with orally available medicines. Pharmaceutical companies realize this portfolio diversification either by expanding or readjusting internal research or by collaborations with biotechnology companies. In either case, preclinical development is often conducted by the larger of the partners, and a comprehensive understanding about the different approaches to either drug class is critical.

Small molecules and macromolecules differ in much more than size, and this overview will discuss the consequences for each stage of drug discovery and development.

With a few exceptions, small molecules are synthesized chemically and are smaller than 600 daltons. For the purpose of this overview, macromolecules are defined as protein molecules of approximately 150 Kd, designed to bind to and functionally affect drug targets. The majority of these macromolecules are antibodies and antibody derivatives, which constitute approximately 25% of therapeutic entities currently in development [4]. Another highly represented class includes receptor fusion proteins. This overview will not describe other large molecules, including therapeutic proteins (naturally existing human proteins used for therapeutic purposes), antisense or siRNA, gene therapy, and others. However, many of the general concepts discussed here can be applied to such drug candidates as well.

The molecular weight and domain structure of antibodies or antibody derivatives are the basis for important limitations and potential advantages when

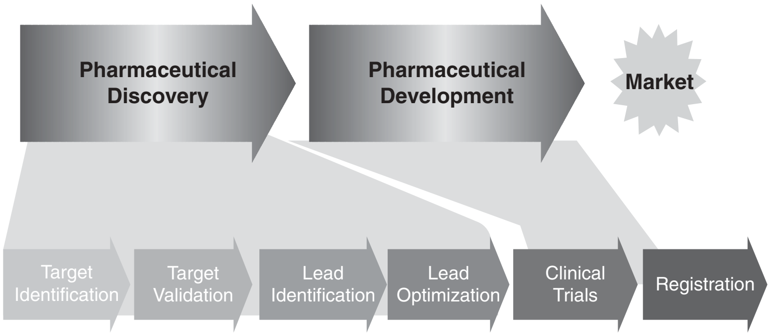

Figure 1.3-1. Critical path in the drug discovery process.

compared with the traditional drug discovery process. Although antibodies are at somewhat of a disadvantage because they are limited to soluble, cell-surface, and tissue matrix targets, their domain structure leads to very significant time-based advantages in the lead finding and the lead optimization phase (Figure 1.3-1).

Drug discovery today relies on the selection of specific and disease-relevant drug targets. Traditional (pre-1990) drug screening, based purely on observed pharmacological effects *in vivo*, has fallen out of favor due to regulatory pressures to conduct discovery research on well-characterized and validated targets. New screening technologies, coupled with the concept of using small molecules to complement gene-based methods of perturbing protein function, has generated renewed interest in this past paradigm and allows for the successful combination of pharmacological drug screening with the identification of specific and potentially new and novel targets in the "druggable genome" [5, 6]. The current general focus toward drug candidates with known mechanisms of action has important consequences for preclinical development. Whereas more standardized safety assessments were appropriate for drug candidates with unknown mechanisms, the understood biology of the drug action today allows and requires an appropriate adjustment at each stage. However, caution about any claim of a "known mechanism" is warranted. Indeed, although the industry worked previously on drug targets with, in some cases, more than 20 years of academic research into target biology, the Human Genome Project has led to work and focus on poorly understood targets. Therefore, drug discovery and development of the future has to undertake target validation work in parallel with drug discovery, consider the assumed mechanism in all formal pharmacology and safety assessments, and maintain the safety net of traditional drug safety studies.

1.3.2 TARGET SELECTION AND DRUG DISCOVERY APPROACHES

The term "target" describes a specific molecular entity, most often a protein, presumed to play a role in the pathogenesis of a disease state. A target can then be

defined precisely with molecular biology tools and can be affected by the action of a specific drug in a manner beneficial to the patient. Estimates place the number of targets modulated by currently marketed drugs at between 120 and 500, with only about 7% of medicines not having a clearly defined target [7]. Target selection starts typically with an analysis of met or unmet medical need and a comprehensive understanding of the pathophysiogical processes underlying the human disease of interest. Companies or academic researchers are typically focused on a limited number of key indications (such as cardiovascular disease, diabetes, autoimmune disease, and cancer) and have significant and relevant internal discovery expertise. This includes, to some extent, novel target discovery and will in most cases include target identification and validation [8]. Indeed, some level of confidence in mechanism-based target validation is a key component of any discovery project considering that, industry-wide, 30–40% of experimental drugs fail because an inappropriate or non-physiologically relevant biological target was pursued [9].

Once a preferred set of targets is identified, the viability and tractability of a small molecule or macromolecule approach can be assessed. In general, differences in physicochemical properties between small and macromolecules may help drive the approach strategy. For example, intracellular and nuclear proteins are often best targeted by small molecules that would more easily overcome cellular permeability barriers in order to reach the desired target. The molecular weight of approximately 150 Kd precludes antibodies from entering cells. Some initial progress has been made to overcome this limitation through the use of viral peptides as vectors for macromolecular delivery into cells [10–15]. Commercially viable therapeutic applications in this direction are not expected to materialize in the short term, because the research efforts are still in the early discovery phase. Another approach under investigation is the use of antibodies directed toward specific internalizing receptors, which can then carry their "payloads" into cells [16]. Cell-surface receptors are often ideal candidates for both small molecule and macromolecule approaches, whereas soluble or circulating proteins are most often targeted by high-affinity macromolecules. Typical selection criteria are summarized in Table 1.3-1 and may be used to determine which technology could be applicable. Additional factors that can influence target selection include those listed in Table 1.3-2. The key point is that the decision of whether to use a small molecule or macromolecule approach within a discovery project needs to be made early in the process, because intrinsic molecular differences will subsequently affect program strategy all the way through to the clinical setting.

The size and structure of small molecules and macromolecules also have very important consequences for some key steps in drug discovery. It is readily apparent that the molecular weight of a drug determines the "footprint" of the drug on the target and related molecules. Macromolecules, including antibodies and receptor-based fusion proteins, have evolved to be able to accurately distinguish between closely related target structures. They can accomplish this by using structural differences on a larger surface area than is typically accessible for small-molecule affinity. Indeed, the footprint of antibodies is estimated to be on the order of about 5 times larger than that of a typical small molecule. However, high specificity requires careful antibody selection and optimization. Desired specificity has to be accomplished while maintaining orthologue (similar gene family member in another species) binding to enable preclinical development.

TABLE 1.3-1. Criteria for Selecting a Small Molecule or Macromolecule Approach

Target Features	Small Molecule	Macromolecule
	Extracellular Location	
Soluble nonenzymatic protein/peptide	–	+
Soluble enzyme	+	(+)[1]
Soluble hormones and mediators	–	+
	–	+
Receptor for protein/peptide (proteinergic GPCR)	–	+
Receptor for nonpeptide hormone (aminergic GPCR)	+	(+)[2]
Pathogen external protein, nonenzymatic	–	+
Pathogen, external protein, enzymatic	+	(+)[1]
	Intracellular Location	
Receptor associated enzymatic proteins	+	(+)[3]
Cytosolic enzymatic proteins	+	–
Nonenzymatic proteins	+	–
Enzymes of pathogenic organisms	+	–

[1] Enzyme inhibitory antibodies are theoretically possible, but evidence is sparse [17].
[2] Agonistic or agonistic antibodies are theoretically possible, but evidence is sparse [18].
[3] Indirect effect by interaction with extracellular receptor portion feasible; no evidence for enzyme inhibitory antibodies [19].
Abbreviation: GPCR = G-protein-coupled receptor.

TABLE 1.3-2. Additional Target Selection Criteria

Target Selection Criteria	Small Molecule	Macromolecule
CNS location	Requires specific compound characteristics for BBB penetration	Required dose to achieve effect *in vivo* may be too high
Homology within protein family	Specificity may be difficult to achieve	Specificity achievable, but orthologue binding required
Druggability	Assessed after high-throughput library screen, consider macromolecule if screen fails	Consider different approaches if the first fails (*in vivo*/*in vitro*)
Protein/protein interaction	Difficult to achieve, but examples available [20]	Often achievable

Abbreviation: CNS = central nervous system.

Another key difference related to size is the difference between small molecules and macromolecules in the degree of interdependence of domains. Although careful evaluation of a structure-activity-relationship (SAR) can readily determine domains in small molecules affecting metabolism, specificity, and other alternative domains, the optimization of these domains will often influence other parameters in a positive or, more often, in a negative manner. In macromolecules, the protein domains are for the most part independent, and optimization of a single parameter, such as specificity in the antigen binding region, will typically not affect half-life, which is determined by a different domain [21–23]. Optimization of small molecules is therefore "multidimensional," whereas macromolecule optimization is, to the most extent, "one-dimensional." For this, and other reasons, drug discovery using macromolecules tends to be more rapid than lead identification and optimization of small molecules.

1.3.3 TARGET PRODUCT PROFILE

The critical role of an early agreement on a target product profile (TPP) for any new discovery project has been reviewed recently [3]. Briefly, a target product profile describes the exact expectations for the drug candidate in specific quantitative terms. The parameters will vary depending on whether the desired molecule would be "first in class" or "best in class" for a given target. For best & in class, the TPP is often more rigorous because the new therapeutic must be demonstrated to be superior to accepted standard-of-care entities (gold standard) currently on the market. In general, the TPP describes the main development objectives in a precise, focused manner. It can serve as a tool for planning and decision making through the course of the research and development program. Ideally it anticipates product claims that can be realistically expected based on preclinical results and can be translated to and confirmed during development. For small-molecule drugs, this includes the proposed mechanism of drug action, specificity, affinity, *in vitro* and *in vivo* potency, pharmacokinetics, tissue distribution, solubility (LogP [less hydrophobic], $LogS_w$ [more soluble]), metabolism, chemical accessibility, acceptable safety profile (both mechanistic and nonmechanistic), and biomarker requirements. For macromolecules, the criteria include mechanism of action, epitope, specificity (including reactivity with relevant preclinical toxicology species), affinity, potency, constant region isotype, effector function readout, expression rate in mammalian cells, stability in typical formulations, side effects, pharmacokinetics from relevant models, and biomarker requirements. Target product profiles should be agreed to by all functions who will be involved in the project during its lifetime, including discovery, preclinical safety, clinical, manufacturing, and others. Modifications of a target product profile should be considered carefully and only based on new data.

1.3.4 LEAD IDENTIFICATION

Table 1.3-3 summarizes the most prevalent key technologies available today for lead identification of small molecules and macromolecules. This landscape is ever-

TABLE 1.3-3. Lead Identification Technologies

Small Molecule			Macromolecule (Antibody)		
Technology	Description	Reference	Technology	Description	Reference
				***In vitro* technologies**	
High-throughput screening	An instrumentation-driven, rapid, high-volume approach to assay single compounds or compound mixtures against a biochemical target	Archer [24]; Bajorath [25]; Kariv [26]	Humanization of murine antibodies	CDR grafting with and without framework mutations	Lo [27]
Affinity screening by mass spectrometry	High-throughput assay technology based on ligand–protein affinity as detected by mass spectrometry	Markara [28]; Comess [29]	Resurfacing of murine antibodies	Selective replacement of surface residues of mouse antibodies	Roguska [30]; Zhang [31]
			Phage display	*De novo* antibody selection from very large and diverse phage libraries	Hoogenboom [32] Marks [33]
Directed and focused combinatorial libraries	Knowledge-driven combinatorial library design and synthesis around target class-related structures	Keri [34]; Miller [35]		***In vivo* technologies**	
			EBV transformed human B cells	Useful for natural or anti-pathogen antibodies, can be combined with phage display	Maeda [36]

TABLE 1.3-3. *Continued*

Small Molecule			Macromolecule (Antibody)		
Technology	Description	Reference	Technology	Description	Reference
Fragment-based screening Example: NMR screening/SAR by NMR techniques	A technique for identifying one or more low-molecular-weight, weak affinity molecules for a given target with synthetic optimization driven toward increasing affinity	Mitchell [37]; Verdonk [38]; Petros [39]; Sillerud [40]	Trioma technology	Selection of human antibodies to pathogen or cancer targets by fusion of patient lymphocytes with a human heteromyeoloma line and subsequent selection in microtiter plates	Vollmers [41]
Virtual screening	The use of knowledge-driven computational selection and scoring methods to identify molecules that have a high probability for interaction with a biochemical target	Alvarez [42]; Anderson [43]	Transgenic mice	Immunization of mice transgenic for portions of the human Ig repertoire followed by traditional hybridoma technology	Lonberg [44]

Pharmacophore modeling	A complementary virtual selection or design exercise based on specific compound class SAR knowledge; uses three-dimensional conformation of molecules and spatial requirements	Guener [45]
QSAR	Mathematical relationships linking chemical structure and pharmacological activity in a quantitative manner for a series of compounds. Methods that can be used in QSAR include various regression and pattern recognition techniques	Lill [46]

Abbreviations: CDR = complementary determining region; EBV = Epstein–Barr virus; NMR = nuclear magnetic resonance; QSAR = quantitative structure-activity relationship; SAR = structure-activity relationship.

changing, and new technological innovations occur frequently. As a caveat, fusion proteins will often use preexisting binding domains (typically receptors) and are not considered in this table.

1.3.4.1 Small Molecules

Collections and Screening. Frequently, a small-molecule drug discovery approach identifies the initial lead molecules primarily by high-throughput screening of vast corporate compound collections against a biochemical target that is associated with a disease state. In general, most pharmaceutical companies will screen between 750,000 to up to 2 million chemical entities in search of a hit set. Although many corporate collections can exceed the 2 million sample mark, it becomes an economic exercise to reduce this, as well as a case of data management to effectively process and act on the results. A variety of innovative high-throughput screening assay formats have been developed that render this process efficient for surveying a reduced set of 500,000 to about 1.5 million entities as either single compounds or mixtures [25]. With increasing pressure to identify and optimize molecules faster, this process has been supplemented with alternative lead identification approaches such as nuclear magnetic resonance (NMR) [39, 40], fragment-based screening [37, 38], and others (*see* Table 1.3-3). Outside of the traditional microtiter plate-based biochemical assays, significant utilization of affinity selection mass spectrometry (ASMS) has become a primary screening paradigm in the past several years. Mass spectrometry-based measurement of small-molecule–protein interaction has subsequently produced results for challenging targets and has provided a cost-effective, rapid method to screen large compound collections while validating hits using plate-based biochemical techniques on smaller subsets [28, 29]. Various *in silico* hit selection techniques have been developed and applied as complementary approaches [47] to minimize the physical number of entities to be tested as well as to optimize the chances, based on appropriate training sets, to identify active chemical space within a large collection. The most common techniques involve a target-based virtual screening process whereby compounds with molecular similarity to known active small molecules are estimated to have affinity toward a biological target binding site as estimated through dock-ing and scoring functions [48, 49]. Selection techniques can be supplemented through the use of pharmacophore modeling [45] and quantitative structure-activity relationship (QSAR) screening [46]. Results with this approach can be limited because it does not initially involve direct biological assay of diverse compounds but a knowledge-based selection of a "high probability" subset of compounds to be screened. A high level of success remains to be achieved for this technique. More frequently, a diverse subset of compounds that should represent "hit-like" and "lead-like" molecules is selected based on calculated physicochemical properties [26]. These compounds are expected to provide ideal starting points for a medicinal chemistry optimization program because they are preselected to have the probability of acceptable solubility, perme-ability, and properties such as molecular weight where they can be subsequently elaborated on and optimized.

To further enhance the chances for success in the screening arena, most pharmaceutical companies have expended considerable effort in acquiring molecules

with hit-like and lead-like properties to improve the quality of their collections [50]. Besides general acquisitions of diverse arrays of molecules, many have also focused on the generation of gene family or target class directed libraries [34], and a slight resurgence in natural products and natural product-like libraries has been seen [51]. Currently on the horizon are the emerging technologies using the concepts of chemical genomics and high content screening, and a variety of industry and academic laboratories are paving the path forward [52].

Hit to Lead. The overall probability that a high-throughput screening (HTS)-derived lead will reach launched drug status is about 1 in a million, shifting the focus of initial post-HTS research efforts toward identifying and characterizing good quality leads [53]. The distinction between hit (compound meeting initial screening criteria) and lead (verified on target activity and selectivity with initial exploration of SAR) is critical [54–56]. It is felt that a rigorous hit to the lead selection process will enhance the probability of overall success. Typical evaluation metrics that a compound series should meet, in order to proceed to lead status, are listed in the points below in Table 1.3-4.

TABLE 1.3-4. Typical Assessment Parameters for Start of Lead Optimization of a Small Molecule

Attributes	Hit-to-Lead Assessment Parameters
Chemical	Reproducible activity between HTS assay and local laboratory assay
	Dose responsive activity
	Confirmed structural identity
	Purity established
	No evidence of compound class instability
	Tractable synthetic route established
	Favorable intellectual property and competitive assessment for compound class
	Demonstrated exploitable SAR
Biochemical	Support for interaction with molecular target (SAR due to desired mechanism)
	Selectivity profile established
Pharmacology	Assessment of druggability and potential attributes that will need optimization
	Secondary assay paradigm established (cell assay, mechanism assay, *in vivo* model, etc.)

Abbreviations: HTS = high-throughput screening; SAR = structure-activity relationship.

With this, it is no surprise that hit to lead has emerged as a unique discipline within many companies, typically built or grown at the expense of the former technology-driven combinatorial chemistry groups. Some companies even have devoted entire departments to the activity so that consistent methods and quality metrics are applied in a rapid time frame [57].

1.3.4.2 Macromolecules

The lead identification process of macromolecules, and especially therapeutic antibody leads, differs for the *in vivo* and *in vitro* approaches (*see* Table 1.3-3). In the case of the *in vivo* approaches, the screening of initial leads occurs through an enzyme-linked immunosorbent assay or through functional assays drawn parallel to the HTS approaches discussed above. However, the number of antibody candidates typically screened is significantly lower because target-specific antibodies have been enriched by the immunization of transgenic mice [44] or preexist in patients. For the *in vitro* approaches, the selection is template based. As an example, the antibodies from phage or yeast libraries are isolated by a process similar to affinity chromatography [32, 33].

1.3.5 LEAD OPTIMIZATION

The biggest difference between small-molecule drugs and therapeutic antibodies lies in the area of lead optimization; however, the overall concepts are very similar. The original leads are optimized in iterative cycles to achieve candidates meeting the pre-agreed target product profile. The drug structure and size makes the lead optimization of small molecules multidimensional (change in one parameter often affects another) and therefore lengthy, whereas the domain structure of antibodies allows for rapid, primarily one-dimensional optimization of the binding and effector regions, where optimization of one has little or no effect on the other.

Although opportunities for macromolecule optimization were limited in the past, antibody technologies today allow one to dial in, more or less, any affinity, potency, or specificity as directed by the target product profile.

1.3.5.1 Small Molecules

In traditional small-molecule drug discovery, hit-to-lead selection is followed by careful, systematic exploration of SAR and *in vivo* compound properties. Iterative cycles of design and data gathering are used, often supported by generating small-molecule–target binding hypotheses using computational resources. For small molecules, this represents the research stage where chemical series with demonstrated affinity of the receptor, enzyme, or protein target of interest are optimized to build in drug-like properties. More properly defined, lead optimization is the synthetic modification of a biologically active compound, to fulfill all stereoelectronic, physicochemical, pharmacokinetic, and toxicologic properties required for clinical usefulness.

This is a joint potency, selectivity, and property optimization process that builds on data (design/analysis cycle) generated during the hit-to-lead prioritization phase and is heavily driven by absorption, distribution, metabolism, excretion, and toxicology (ADMET) and physicochemical property profiling as early as practical. Combinatorial or parallel synthesis techniques resulting in the generation of scaffold-targeted libraries are often used to understand and develop both the chemical and the intellectual property (IP) space. If amenable, specific analog design guided by QSAR or homology modeling hypotheses is incorporated. It is

preferable to have more discrete structural information either from protein NMR studies or ligand/target x-ray crystallography if tractable for the target.

In the effort to choose and accelerate programs that offer the best possible chance to move forward, a value and risk assessment at the start of lead optimization typically occurs along with project and resource prioritization (Table 1.3-5).

TABLE 1.3-5. Typical Assessment Parameters for Start of Lead Optimization

Priority	Lead Optimization Assessment Parameters	Small Molecule	Macromolecule
1st	Potential for therapeutic advance	+	+
	Commercial potential/market size of indication area	+	+
	Competitive environment	+	+
	Intellectual property position	+	+
	Relevance of target for disease	+	+
	Feasibility of biological predictive preclinical model	+	+
	Quality of lead candidates (several dimensions, *see* hit-to-lead criteria)	Specific	Specific
2nd	Target related tolerability	+	+
	Fit to therapeutic area strategy/portfolio	+	+
	Clinical trial design feasibility	+	+
	Amenability of rational or structural drug design	+	−

The chemistry strategy involves defining critical regions of the molecule that can be identified as interacting with the specific amino acid residues of the targets in a three-dimensional model and thus drives potency and selectivity. Areas of the molecule that are SAR "neutral" can be found, which can be used as positions to alter the net physicochemical properties. Small modifications will often affect the *in vivo* bioavailability, the metabolism profile, and the absorption properties of the molecule. Optimization of chemical entities is therefore always multidimensional, and a compromise must be reached before preclinical candidate selection can occur. Any improvement in specificity may be gained with the loss in absorption or half-life, a correction of which will again have effects on specificity. Because of the many iterations of changes and retesting, traditional drug discovery projects are typically long and very costly. Not infrequently, non-mechanism-related toxicity is observed later in development and is not predicted based on the assays available preclinically. To address some of these complications, new methods for predictions of half-life and toxicity are being developed [58]. Introduction of early experimental ADME testing has been credited with significant improvements in the probability of successful lead optimization [59, 60] and is now a widely used practice. To date, the crucial component to small-molecule discovery is the ability to assess, as early as possible, the potential for ADMET failure. The key is to "fail fast" in order to minimize the substantial total research and development investment and costs incurred in the process of learning the shortcomings of a candidate at the clinical trial stage.

1.3.5.2 Macromolecules

Macromolecules, like antibodies, have a defined domain structure separating the domains for specificity and affinity (Fv) from the constant region domains responsible for half-life (Fc receptor [FcRn] binding domains) [61] and effector functions (antibody-dependent cellular cytotoxicity [ADCC] and complement-dependent cytotoxicity [CDC]) [62]. This separation is important because optimization can be done in the first instance in "one dimension." Extensive variation of the complementary determining region 3 (CDR3) regions of the heavy or light chain to increase affinity will in most or all cases have no affect whatsoever on half-life or effector functions of the antibody. Similarly, changes in the half-life or effector functions typically would not affect the affinity. However, examples of interaction between the Fc domain and the Fv antigen binding site have been reported [63, 64] and can be monitored and ruled out by appropriate testing at each stage of optimization. It is easy to see that this one-dimensional optimization should be more straightforward.

Antibody optimization of the antigen binding portion should focus on hypervariable regions, primarily both the heavy- and the light-chain CDR3 regions and preferably the heavy-chain CDR3, as not to introduce undesirable epitopes. Older methods for antibody optimization include a variety of mutation and selection techniques [65], most of which are tedious. The optimal method is yeast display, combining rapid library creation and rapid selection using cell sorters, with a wide range of selection options (selection for optimal "on-rate," "off-rate," "affinity," etc.) [66, 67]. Other methods include ribosome display [68]. Fc optimization includes optimization of effector functions [62] and half-life [21]. Interestingly, the differential effects of Fc mutants on either Fc effector functions (ADCC or CDC) or half-life is further proof that the overall concept of one-dimensional antibody optimization remains correct. This notwithstanding, careful analytical follow-up at the end of the project or at appropriate intervals with meaningful and well-characterized assays will ascertain that indeed no change in functions of another domain has occurred. Because of the specificity and lack of accessibility to intracellular targets, antibodies typically are devoid of nonmechanistic toxicity, which further reduces the discovery and development risks. However, meaningful and appropriate safety testing still will be necessary to assure the safety of therapeutic antibodies [69].

1.3.6 SELECTION OF CLINICAL CANDIDATES AND PRECLINICAL DEVELOPMENT

Selection of clinical candidates and the identification of new chemical entities or new biological entities that best match the TPP is a multidisciplinary task that relies heavily on *in vitro–in vivo* correlations. For first-in-class targets, mechanism of action validation (target validation) research typically parallels the lead identification and lead optimization phases of any drug discovery project. For best-in-class targets, the preferred initial small-molecule validation reagents are competitor's leads or gold standard therapeutics currently on the market, their own initial screening leads, or monoclonal antibodies to the target orthologue. As the project

progresses, target validation continues with the drug leads until the *in vivo* data in relevant disease models meets the expectation set out in the TPP. For macromolecule discovery projects, target validation requires either surrogate antibodies or drug leads that cross-react with the orthologue of the preferred pharmacology model species. Usually, a small series of candidate molecules that best match the TPP set at the initiation of the project are subjects of consideration. Outliers are also considered if they can provide unique insight or datasets that might challenge the original TPP, because potential opportunities may not have been realized at the outset of the program. As the project progresses, target validation continues with the selected drug leads until the *in vivo* data in relevant disease models meets the expectations set out in the TPP. For macromolecule discovery projects, target validation requires either surrogate antibodies or drug leads that cross-react with the orthologue of the preferred pharmacology model species.

The topics in Table 1.3-6 are frequently evaluated as part of the risk assessment before starting development activities. Comprehensive *in vivo* efficacy and preliminary safety testing, preferably in multiple species, with simultaneous pharmacokinetic assessment is typically the last dataset collected before making a decision on a development candidate and possible back-up compounds. The Core Battery for safety pharmacology, which can be found in the International Conference on Harmonisation (ICH) Guideline S7A (Good Laboratory Practice [GLP]) document series [70], governs safety assessment and data generation guidelines. The suitable second (nonrodent) toxicity species should be identified in combination with drug metabolism, pharmacokinetics, and pharmacology studies in that species. An overall evaluation of the toxicity and toxicokinetic data should be undertaken to understand the risk for adverse effects, target organ issues, and systemic exposure liability. This should allow researchers to set a preliminary limit dose (mg/kg in relation to C_{max}) for toxicity studies and give recommendations for further

toxicity assessments. The assessment also should include data from predevelopment lead optimization work. For small molecules, the 2-week toxicology study in rodents, including toxicokinetic data, should be suitable as dose-range finding for further repeat-dose (4 week) studies. If performed according to GLP, the safety data from the 2-week study could support phase I. Optional toxicity studies at this stage can include, but are not limited to, single-dose toxicity (GLP, rat) and genotoxicity tests (GLP, Ames, mouse lymphoma) [71, 72].

Early interaction with process research and development teams allows for intermediate-scale synthesis and production of material required for these advanced studies and will enable an assessment of any possible issues around scale-up, cost of goods, stereochemical issues, and compound solid-state crystallinity and stability. Selection criteria are often rigorous, and given the multidisciplinary nature of the profiling, collaborative, tightly scheduled efforts are required across research and development department structures. The preferred criteria set for candidate molecules include those listed in Table 1.3-7.

A discussion of regulatory requirements for the preclinical safety assessment of drug candidates intended for use in humans would require significant detail. The reader is referred to excellent resources and websites (www.ich.org, www.fda.gov, and www.emea.com) for detail and additional information.

Although the safety assessment of small-molecule drug candidates is more standardized, the preclinical program for a macromolecular biological medicine requires adaptation (i.e., case-by-case and highly tailor-made approach), simultaneously meeting the basic requirements for types of studies, duration, and exposure [73–75]. The key principles are outlined in ICH guidance S6 and Center of Biologics Evaluation and Research (CBER) 1997, and some key highlights are summarized in Table 1.3-8 [76, 77].

1.3.7 PRODUCTION OF ACTIVE PHARMACEUTICAL INGREDIENTS

Differences in structural complexity, continuous versus stepwise production, and the overall production techniques and equipment results in significant differences between the manufacturing of small and macromolecule bulk drug substances or active pharmaceutical ingredients (APIs). In addition, continuous improvement of analytical tools is changing the landscape of both process types over time. Small-molecule synthesis consists typically of 6 to 10 (or more) separate synthetic steps, whereas macromolecule production consists of 15 to 20 connected steps. Each step in small-molecule synthesis carries its own risk, but because they are separate or can be separated from each other, low efficiency or failed steps can be repeated, thus minimizing loss. On the macromolecule side, the process is continuous and all steps are directly linked. Failure at any step will typically result in complete batch failure. Another key difference is that small-molecule process research can and often begins during the lead optimization phase of research. This "front-loaded" model [78] is in place in many companies, and initial research toward the efficient production of a promising chemical series is initiated, at risk, early on. With a macromolecule, typically the final sequence or composition of the candidate molecule must be clearly identified so that appropriate constructs can be generated and then optimized for fermentation processes.

TABLE 1.3-7. Criteria for Development Candidates for Internal Decision Making

Criteria	Small Molecule	Macromolecule
	Chemical Manufacturing and Control	
Synthetic accessibility	Synthetic steps, chiral centers, reagent cost of goods	—
LogP	$-4 \le \log P \le 4.2$	—
LogSw	≥–5	—
Formulation	Project specific	≥50 mg/mL
Production yields	Project specific (overall cost of goods)	50–100 pg/cell/day
	In Vitro Pharmacology	
Cell assay potency with and without serum	Project specific	Project specific
Protein binding	Availability required	—
Target specificity	Specificity within close and distant target family members	ELISA specificity within diverse set of related proteins
Affinity	Project specific	BiaCore $>10^{-10}$ M
Tissue cross-reactivity	—	Binding to tissues with known target expression
	In Vivo Pharmacology/PK/PD/ADMET	
Efficacy in relevant model at appropriate dose, route, and schedule	Project specific	Project specific
Metabolites	Identified and characterized	—
PK/PD relationship	Project specific	Availability desired
Biomarker for PD effect	Availability desired	Availability desired
No overt toxicity in repeat dose (1 to 4 week); toxicity studies in a rodent and nonrodent species	Availability required	As follow-up for unexpected pharmacological observations
Drug–drug interaction	No significant interactions	—
Human CYP inhibition	No relevant interactions; also consider comedications	—

Abbreviations: ADMET = absorption, distribution, metabolism, excretion, toxicology; CYP = cytochrome P450; ELISA = enzyme-linked immunosorbent assay; PD = pharmacodynamics; PK = pharmacokinetics; — = not applicable.

TABLE 1.3-8. Key Issues Around the Designs of Safety Studies [76, 77]

Issue	Small Molecule	Macromolecules	Guidance for Macromolecules
Selection of relevant animal species	Typically 1 rodent and 1 nonrodent species	Studies in irrelevant species are of no value or might even be misleading. Criteria for species selection include: • Tissue cross-reactivity studies comparing human and animal tissues • Pharmacologically active (i.e., expressing the appropriate epitope or receptor)	• Closest pattern to human tissues defines animal species • One species (often the monkey) might be sufficient; if no species available, use of a surrogate and/or transgenic animal might be appropriate • Early and close interaction with agencies highly recommended
Dose level selection	Based on the anticipated highest clinical dose, high dose should show toxicity		Three dose groups plus a control group with multiples of anticipated highest clinical dose (e.g., 2, 10, and 50 times clinical dose); high dose selection often not driven by toxicity
Treatment frequency	Should parallel the treatment regimen in humans		Depending on PK and immunogenicity, a higher dose frequency might be needed to achieve comparable exposure
Local tolerability	With oral dosing not an issue	Application route predominantly IV and/or SC; it is important to test the clinical formulation	Visual inspection and histopathology of injection site
Recovery period	Long enough to allow clearance of the drug		At least 5 half-lives; can be up to 3 months
Immunogenicity	Not an issue	Induction of ADA, characterization (i.e., neutralization, impact on drug exposure because of increased clearance) At high dose level immune response often suppressed	• If exposure decreases due to ADA formation, no adequate long-term treatment might be possible • In general, animals are not predictive of immunogenic response in humans

Genotoxicity studies	Standard battery	Not applicable	Interactions with DNA or chromosomes is not expected; large amounts might even lead to uninterpretable results
Safety pharmacology	Standard core battery	For mAbs, generally not necessary. If cause of concern (e.g., cross-reactivity with CNS, CV, or respiratory tissues), specific study might be indicated	As many parameters as possible to be included in toxicology study. A study in telemetrized animal to address CV and respiratory endpoints might be an alternative approach
Carcinogenicity	Required	Not applicable	The standard carcinogenicity bioassays in rat and mouse are generally inappropriate
Reproductive toxicology	Standard package (Fertility,embryo-fetal toxicity and peripost natal toxicity)	Dependent on product, intended use and patient population. Study must be conducted in relevant species. Expectations from authorities still different for U.S., EU, and Japan regarding timing of the studies	The primate is often the only relevant species; however, because of the small numbers of animals available and the lack of a broad dataset, testing of a rodent homologue might be an alternative U.S. not required to support phase I/II
ADME	Standard battery *in vitro* and *in vivo*	Not applicable	Not relevant as the drug enters the normal proteolytic degradation pathway
Biomarkers	Should be included whenever possible to demonstrate the intended pharmacology of the drug		PK/PD relationship helps to define safety margins as well as selection of dose level and regimen

Abbreviations: ADA = anti-drug antibodies; ADME = absorption, distribution, metabolism, excretion; CNS = central nervous system; CV = cardiovascular; EU = European Union; IV = intravenous; mAbs = monoclonal antibodies; PD = pharmacodynamics; PK = pharmacokinetics; SC = subcutaneous; U.S. = United States.

1.3.7.1 Small Molecules

As discussed, pressure to move new medicines to the market faster has compressed many aspects of the research and development cycle. Process research initiates their search for scalable routes early in the discovery programs in the hope of having an efficient or semi-efficient route to prepare up to 100 kg of API as a program nears the final preclinical stages and prepares for phase I studies in humans [79].

Although any synthetic transformation or use of a specialized reagent can be scaled up, cost and safety are two primary driving factors in the manufacturing process. In a recent survey of GMP bulk reactions run in the last several decades, a predominant subset of transformations were shown to fall into favor [80], with less than a 2% change within the categories. This result indicates that significant process research efforts are often required to advance an initial medicinal chemistry analog synthesis route to one that is amenable for use in large-scale production. Once route selection occurs at phase I, synthetic efficiency is critical and reactions must be controlled so that consistency of yield and purity is ensured, especially as a program nears phase II in the clinical setting. This is the point at which the process for generating the API must be finalized and approval packages initiated for the regulatory agencies. To control costs, many manufacturers will partner with specialty firms to transform key synthetic intermediates in the stepwise production process toward the final API (which is almost always prepared within the company's facility to meet regulatory requirements). Such external, contract synthesis often involves sensitive or specific technology-based transformations or separations for purification that would have significant cost impact if a production facility needed substantial capital improvement and/or steep licensing fees to conduct. Environmental aspects of production also have become increasingly important. Considerable steps are taken to minimize waste streams, and the advent of "green chemistry," a move to decrease usage of organic solvents in favor of water, when appropriate, is actively under investigation [81]. In addition, energy-efficient methods and technologies such as microwave-driven processes are being explored to accelerate cycle times [82] within synthesis routes.

Small-molecule manufacturing is also a system of checks and balances in which any small increase or decrease in reaction step performance can have consequences downstream. As always, patient safety is of utmost concern. Any manufacturing process changes that alter an impurity level or introduce a new impurity, even as low as 0.1%, may necessitate additional toxicity studies and documentation for review and registration. In addition, an improvement in reaction efficiency may alter bulk product crystallinity or polymorph composition that can affect formulation and human pharmacokinetics. Once process parameters are finalized, the ultimate manufacturing step involves selection of a manufacturing site, transfer of the process, and preparation of a demonstration batch followed by a minimum of three consecutive validation batches of API to demonstrate that the synthesis of material can be controlled within analytical specifications and reproducibility.

1.3.7.2 Macromolecules

Macromolecules, including therapeutic antibodies and fusion proteins, are complex molecules requiring extensive analytical characterization. Native antibodies com-

prise a heterodimer of two light and two heavy chains with a single N-glycosylation site in the heavy-chain constant region. Proper assembly and glycosylation is important for antibody function. Fusion proteins often consist of natural binding proteins (such as receptors) fused to the nFc (CH2 and CH3 IgG domains) region. Due to interchain disulphide bridges, Fc-fusion proteins assemble into homodimers. The complexity of fusion proteins depends on the structure of the ligand binding domain and the number of N-glycosylation sites. The single N-glycosylation site in antibodies is "buried" into the opposite heavy chain constant region, whereas the carbohydrate residues on ligand binding portions of Fc-fusion proteins are exposed and may have a pronounced effect on the *in vivo* behavior of the molecule. For these reasons, full-length antibodies and fusion proteins should be expressed in mammalian cells. Modified yeast systems capable of appropriate glycosylation and fungal systems have been proposed [83]. By contrast, antibody fragments have been expressed successfully in *Escherichia coli* and yeast. Decisions for an expression system should be based on the complexity of the molecule, the specific biological activity achieved with a given system, and the appropriate technical, IP, and regulatory considerations for manufacturing at scale. Expression of therapeutic antibodies in a variety of systems has been reviewed recently [84, 85]. Methods include transgenic animals [86], expression in plants [87], or the more standard myeloma systems [88] or CHO cell expression [89]. The recovery and purification of therapeutic antibodies also has been reviewed recently [90]. For the reasons discussed, when designing purification schemes, attention should be paid to reduction of aggregation and DNA content, especially if bacterial systems are involved, to minimize any immunogenicity risks. In each case, a defined set of assays needs to be applied to the purified final product to ascertain the purity and specific activity of the expressed antibody. This is especially important if reconstitution and refolding is part of the process [91].

Historically, macromolecule products were characterized with a limited set of tools and additional methods beyond that were defined by their specific process. This led to complications when changes in the process were desired. A chance event changed this landscape. Briefly, biotechnology company Biogen, Inc. (today Biogen Idec, Inc., Cambridge, Massachusetts) and the Rentschler daughter company, Bioferon GmbH (Laupheim, Germany), formed a joint venture in 1984 for the clinical development of interferon-beta, called BG9015. Rentschler was responsible for the creation of the cell line and production and Biogen for clinical development, which commenced in 1990 with a U.S. clinical study in patients with multiple sclerosis. When this joint venture failed in 1993, Biogen completed the initial trial with the remaining BG9015 and switched to BG9216 from their own process. After the U.S. Food and Drug Administration (FDA) determined that these products were not identical, a new process for what is today called Avonex (interferon beta-1a; Biogen Idec, Inc.) was approved and was considered sufficiently identical with the original BG9015 for the original study results to be considered as part of the Avonex biologic license application. Extensive biological, biochemical, biophysical, and human pharmacokinetic data were the basis for the FDA conclusion that BG9015 and Avonex were "biochemically and functionally equivalent," leading to Avonex approval on May 17, 1996 [92]. This decision created a path for others to follow, leading to a fundamental change in macromolecule production and ushering in the concept of "well characterized biologic" [93]. Increasingly sophisticated analytical

techniques have facilitated process changes even further, and today, macromolecules require very detailed characterization, resembling more and more the requirements for small-molecule pharmaceutical ingredients [94]. Indeed, analytical tools have become so sophisticated that much of the current dispute on biogenerics (or "follow-on biologics") focuses on the true equivalence of macromolecule products [95].

1.3.8 FORMULATION AND DELIVERY DEVICES

Drug product development takes place in a highly regulated environment with a clear expectation for quality, safety, and efficacy in the final product. From a formulation perspective, quality primarily translates into a defined composition, assurance of purity, potency, an acceptable stability, and availability of a robust and consistent large-scale manufacturing process. Thus, the ultimate goal of formulation activities is to achieve the systemic delivery of a drug product that can be successfully commercialized. Product life-cycle management strategies are considered at the beginning of development and often include evaluation of specialized administration devices for parenteral (injectable) products, especially for macromolecules. If these options are considered early in development, a product family can often be designed to minimize subsequent development efforts by using a common platform (e.g., prefilled syringe-based autoinjectors). One challenge in the development of devices is a thorough understanding of the limitations of the device, limitations of the formulation, and finding the right compromise between both. Also, one has to keep in mind that the regulatory path for devices and fixed-device drug combination products is different, and significant differences exist among the major markets such as the United States, the European Union, and Japan.

The scope of formulation activities is dependent on the development stage of the drug substance. In general, the development process can be divided into three major phases, namely formulation support of discovery, formulation activities until clinical proof of concept (end of clinical phase IIa), and formulation activities in the commercial phase (phase IIb until market).

1.3.8.1 Formulation Support in Discovery

Formulation support in discovery usually starts at the lead optimization phase with a focus on key properties of molecules to support selection of the best candidates. The preferred route of administration for small molecules is oral, which requires the development of a solid dosage form. Because only dissolved molecules can be absorbed, assessment of solubility is of prime interest. In general, macromolecules are not orally absorbed and a parenteral dosage form is required. Some proteins, like monoclonal antibodies, often require high doses, and therefore, it is important to understand the solubility range for the protein in question. Compared with small molecules in which established strategies exist for tackling solubility problems on the basis of chemical modifications, solubility issues with proteins are mechanistically poorly understood and very difficult to address on a molecular basis. Most small-molecule drug candidates are crystalline in nature, whereas macromolecules are usually dissolved in aqueous media. The composition/formulation of the solution determines the properties of the protein, and therefore, a basic understanding

about suitable pH ranges, temperature sensitivity, buffer composition, and so on, is important. These parameters have to be defined and controlled early in the discovery phase. The complex molecular structure of proteins poses a significant challenge to the analytical techniques and the ability to detect the instabilities of the molecule. Characterization of degradation products is a prerequisite to understand the major degradation pathways of the protein, which will enable a rational design of the formulation. Degradation pathways of proteins include deamidation, oxidization, hydrolysis, fragmentation, and aggregation. Formulation strategies have been developed to address these instabilities and can act as guiding principles in early development phases. Once the selection of clinical candidates has been initiated, the number of drug molecules will be narrowed down significantly and profiling of the proposed candidate for development can take place. For oral small molecules, solid-state characterization is a very relevant topic for a solid dosage form as summarized in Table 1.3-9. For a protein delivered parenterally, it is

TABLE 1.3-9. Formulation Attributes at the Development Project Stages

Stage	Small Molecule	Macromolecule
	Discovery Stage	
Common dosage route (all stages)	Oral	Parenteral
Critical factors to optimize	Bioavailability, solubility, logP, permeability, absorption	Bioavailability, solubility, pH stability, freeze/thaw behavior
Physicochemical attributes	Crystalline solids or salts	Solution stability, aggregation
	Early Development Stage	
Common dosage form	Powder in bottle, tablets	Lyophilized powder in bottle
Critical factors to optimize	Dosage form	Temperature sensitivity and storage conditions, dose per unit and dosage form
Physicochemical attributes	Crystal polymorphism, solid-state stability, optimized salt selection	Conformational stability, buffer formulation, surfactant or excipient stability, aggregation
Device	Tablet, capsule, oral suspension or solution	Prefilled syringe
	Commercial Stage	
Develop commercial process	Yes	Yes
Batch scale-up	Yes	Yes
Batch stability	Yes	Yes
Process validation	Yes	Yes
Establish commercial supply chain	Yes	Yes

important to define the composition of the drug substance. Ideally, the drug substance composition should be as simple as possible to allow for flexibility in later development phases. In the most simple situation, the drug substance composition consists of a protein (concentration at least half of the highest single dose for first in human studies), a buffer system (suitable for parenteral administration) in a pH range of 5 to 8, and a surfactant, if necessary.

1.3.8.2 Formulation Activities Until Clinical Proof of Concept

For early clinical trials, preliminary dose formulations or "clinical service forms" are developed. Small-molecule oral products can be either powder in a bottle or oral solutions/suspensions. Proteins are usually initially formulated as lyophilized powders that maximize long-term stability at the expense of a lesser convenient dosage form due to the necessity of the reconstitution step. Parenteral dosage form manufacturing requires a highly technical and sophisticated infrastructure, including highly trained personnel and well-established GMP systems in order to assure sterility of the products. These requirements limit flexibility in the development of parenterals compared with oral products. Temperature stability studies have to be conducted to justify use of material that has experienced temperature variations on storage. This is usually not an issue for small molecules, but sometimes specific safety considerations are more important and require special handling and shipment conditions.

During the course of the early clinical development program, a more detailed definition of the commercial product evolves. The most important information is the dose per unit and the specific dosage form. Oral products often require modified release dosage forms in which extensive pharmacokinetic modeling/testing of prototype formulation have to be performed. For parenteral products, self-administration and convenience is becoming more and more an expectation. Prefilled syringes that allow subcutaneous administration of liquids satisfy this need. The main issues involved with development of a liquid protein formulation in a prefilled syringe are using volumes less than 1 mL (consequently, protein concentration can be as high as 100–200 mg/mL), aggregation of proteins due to the high protein concentration, viscosity issues, interaction of the protein with silicone oil present in the prefilled syringe, and the higher chance of chemical degradation in a liquid solution. Aggregation of proteins and conformational stability is a major obstacle because reliable detection of small amounts of aggregates is analytically challenging and aggregates or conformationally altered protein molecules are suspected to be involved in undesired immunogenic responses to therapeutic proteins. Conformational changes can be induced by small changes in drug substance/drug product manufacturing. Therefore, changes in manufacturing have to be carefully evaluated on product impact and often require additional stability testing because the impact is not predictable.

1.3.8.3 Formulation Activities in the Commercial Phase (Clinical Phase IIb until Market)

The main activities are similar for small molecules and macromolecules at this stage. The primary focus is in the areas of scale-up, generation of primary batches

for stability testing, and development and validation of the commercial manufacturing process.

For solid dosage forms, scale-up is a major challenge and includes ensuring the bioequivalency of the clinical product to the commercial product. For proteins, shear-induced aggregation can be an issue, as well as establishment of a commercial supply chain that is robust, reliable, and able to deal with large amounts of temperature-controlled materials.

1.3.9 CLINICAL DEVELOPMENT

There are differences in the pharmacokinetic properties of typical small molecules and monoclonal antibodies that will affect the clinical development path. A few of the differences are listed in Table 1.3-10. Small molecules are usually administered orally, which is desired because of convenience for patients. On the other hand, the administration of monoclonal antibodies is limited to the parenteral route, i.e., intravenously (*i.v.*), intramuscularly (*i.m.*), or subcutaneously (*s.c.*). Because of the availability of liquid formulation or reconstituted lyophilized powder to support parenteral administration, measurement of absolute bioavailability after *s.c.* or *i.m.* administration is necessary for monoclonal antibodies. The relative bioavailability is usually obtained for small molecules because of the expense of developing liquid formulations. Both renal and hepatic clearance pathways are important for elimination of small molecules, and an understanding of drug disposition in patients with renal or hepatic impairment is important to support the registration documentation. Small molecules are often metabolized in the liver by cytochrome P450 enzymes; therefore, drug–drug interaction studies are an important component of the clinical data package. Therapeutic monoclonal antibodies follow the typical pathway of elimination for immunoglobulins (IgGs), involving the neonatal (FcRns). Briefly, endothelial cells lining the blood vessel are thought to be the major site of IgG homeostasis, with the FcRns acting as salvage receptors,

TABLE 1.3-10. Differences Between Small Molecules and Therapeutic Monoclonal Antibodies that Can Affect Clinical Development

Small Molecules	Monoclonal Antibodies
Usually administered orally	Given parenterally
Transporters often important for disposition	Transporters are not important for disposition
Metabolism by hepatic cytochrome P450	Proteolytic degradation
Renal clearance often important	Renal clearance is not important for molecular weight higher than 20 Kd
Half-life is shorter (usually <24 h)	Half-life is long (1–3 weeks)
PD usually does not affect PK	PK can be dependent on PD
Immunogenicity is a not an issue	Immunogenicity is an important issue

Abbreviations: PD = pharmacodynamics; PK = pharmacokinetics.

protecting IgGs against lysosomal degradation. The IgGs are taken up by endothelial cells by nonspecific pinocytosis and then enter acidic endosomes. If the IgG is bound to the FcRn, then it is protected and released back into the blood stream; otherwise, it is degraded. Thus, the FcRns serve the dual function of transcytotic shuttle (i.e., placental transfer, etc.,) and homeostat [22, 61]. As long as therapeutic antibodies bind to the FcRns, they are thought to participate in this pathway. Whether modulation of that interaction by mutating the IgG Fc portion can predictably extend or shorten IgG half-life is the subject of ongoing research. Metabolic interactions such as inhibition or induction of cytochrome P450 enzymes are usually not a consideration. Transporters must be a consideration for the understanding of the disposition of small molecules, whereas except for FcRns transporters, transporters are of lesser concern for monoclonal antibodies.

Allergic reactions are a potential issue for both small and large molecules. The potential for development of significant levels of antidrug antibodies needs to be considered for any recombinant protein, including fusion proteins and monoclonal antibodies, regardless of whether the therapeutic antibody is chimeric, humanized, or fully human. Assessment of immunogenicity begins in phase I and continues throughout clinical development. Incidence of immunogenicity can differ for each patient population and should be assessed for each indication. The development of assays to assess immunogenicity begins before filing the investigational new drug application. Validated assays are necessary by phase III. In the case of fusion proteins, the cross-reactivity of antidrug antibodies with the endogenous human protein in the patient needs to be considered.

1.3.10 INTELLECTUAL PROPERTY

Farnley and colleagues [96] have recently reviewed the complexity of intellectual property around biotechnology and biotechnology products. The authors note that the IP issues for small molecules and macromolecules, with a few exceptions, may be more similar than commonly assumed. The most important difference relevant to this overview is that each step in the discovery process may potentially be subject to different intellectual property considerations, which the authors note as unusual. The major differences between small-molecule and macromolecule patenting are shown in Table 1.3-11.

TABLE 1.3-11. Intellectual Property Considerations for Small Molecules and Macromolecules

Patents	Small Molecule	Macromolecule
Target	Yes	Yes
Drug class (“antibody to target X”)	No	Yes
Substance	Yes	Yes
Drug screening	Yes	Yes
Drug synthesis steps in discovery stage	No	Yes+

1.3.11 GENERICS, “BIOSIMILAR PRODUCTS,” OR “FOLLOW-ON BIOLOGICS”

Although a full assessment of generics is beyond the scope of this introduction, the differences between small-molecule and macromolecule generics are highlighted briefly in Table 1.3-12. Importantly, the terminology “generics” should not be used for noninnovator developed off-patent macromolecules. They are not “generic” in the true sense, and “biosimilar products” or “follow-on biologics” are the more appropriate terms. Reasons include the independently developed manufacturing process, the resulting possible differences in product heterogeneity, and the need for preclinical and clinical development. Many companies around the world are working toward registration of off-patent recombinant proteins. Interferons, human growth hormone, and erythropoietin are some of the more popular therapeutics that are targeted.

The development path for small-molecule generics has been clear for many years. In contrast, the path for biosimilar products or follow-on biologics has only recently been clarified in Europe (October 2005), and regulatory uncertainty remains in the United States. The new European guideline 2004/27/EC clearly

TABLE 1.3-12. Regulatory Criteria for Biosimilar Products or Follow-On Biologics

	Small Molecule[1]		Macromolecule	
Terminology	Generics		Biosimilar products or Follow-on biologics	
	U.S.	EU	U.S.	EU
Regulatory framework	21 CFR Part 314 Subpart C.	Article 10 (1) of Directive 2001/83/EC	TBD	Annex I to the Directive 2001/83/EC and 2004/27/EC
Application and review	ANDA in CTD format FDA moving to QbR by 1/07	CTD format	TBD	CTD Agency consultation by “scientific advice request” strongly recommended
Nonclinical studies required	No	No	TBD	Yes
Clinical studies required	No	No	TBD	Yes

[1] Including some small proteins/peptides in the United States (e.g., insulin, human growth hormone).

Abbreviations: ANDA = Abbreviated new drug application; CFR = Code of Federal Regulations; CTD = Common technical document; EC = European Commission; EU = European Union; FDA = Food and Drug Administration; QbR = question-based review; TBD = to be determined; U.S. = United States.

anticipates a more or less full development program for biosimilar products or follow-on biologics, with material from the sponsor's manufacturing process compared with the innovator reference product.

Importantly, for registration in countries of the European Union, the sponsor of a follow-on biologic has to develop a process generating a protein sufficiently similar to the reference product without access to the typically trade-secret-protected innovator's manufacturing process or the manufacturing cell banks. In addition, a significant nonclinical safety and clinical program has to be conducted.

No biosimilar products/follow-on biologics have been approved in the United States, European Union, or Japan to date. Products confusingly referred to as "generic interferon alpha-2b" or "generic human growth hormone" available in some countries in Asia, Eastern Europe, and Mexico were registered after completion of clinical studies and not through the process used for small-molecule generics. In January 2006, the European Medicines Agency (EMEA) issued a positive opinion for the Novartis subsidiary, Sandoz GmbH (Holzkirchen, Germany), application for the recombinant human growth hormone Omnitrope (somatropin) as biosimilar to the already marketed reference product Genotropin.

1.3.12 SUMMARY

Biologics-based medicines have become an increasingly important part of the armamentarium available for physicians to therapeutically manage disease. Many promising new entities are in various stages of discovery and development. Although some conceptual differences between small-molecule and macromolecule drug discovery have decreased over recent years, the fundamental overall structural differences dictate unique approaches for each.

Previously, macromolecules were used with little or no optimization, whereas small-molecule and macromolecule discovery today are both geared toward developing the optimal molecule that meets the precise needs of the underlying biology. In mimicking natural processes, biologics, and especially antibodies, can be optimized in all binding characteristics without limitation. The overall discovery/development process can be divided into four convenient steps:

1.3.12.1 Step 1: Target Selection and Validation

Successful drug discovery generally starts with the definition of a well-defined and biologically understood target. Importantly, the role of the target in disease needs to be demonstrated with unequivocal target validation studies and the role in normal physiology and existence of variants or closely related family members needs to be investigated. Drug discovery today often fails because targets with uncertain biology are being pushed into drug discovery too early.

1.3.12.2 Step 2: Choice Between Small-molecule and Macromolecule Platforms

At this phase of the discovery process, the biology and location of the target, the disease, and the commercial goal should drive the decision of whether a small-

molecule or biologics discovery approach is optimal. Overall, the management of a mixed portfolio using both drug discovery platforms needs to be considered in light of managing a risk-balanced portfolio. Biologics benefit from a more rapid discovery process and a higher probability of success, with one factor being the lack of nonmechanistic toxicity, often leading to first-in-class commercial opportunities.

1.3.12.3 Step 3: Definition of Target Product Profile

Once the target is defined and the technology platform selected, the TPP needs to be defined. The TPP is an agreement between all stakeholders in drug discovery, development, manufacturing, commercial, and others on the specific goal of the project considering all phases of development. The TPP lays down in detail the expected characteristics of the development candidate considering the needs of a formal preclinical program. As an example, if the biologics discovery project does not consider cross-reactivity with an orthologue in the planned toxicology as important, the final candidate may bind to the human target only and face huge hurdles in development.

1.3.12.4 Step 4: Drug Discovery and Development

With key decisions from Steps 1–3 complete, drug discovery using either platform can proceed. It is critical that target validation work continues throughout this period. The TPP planning discussed under Step 3 helps to anticipate reagents needed much later, but it may be time consuming to prepare (e.g., transgenic mice with human target proteins for pharmacology studies).

In contrast to the previous decade, biologics-based medicines can be finely tuned to meet challenging affinity, potency, or specificity goals, and large advances have been made toward dialing in appropriate half-life and effector functions. Antibody affinity optimization, for example, if attempted at all, may have taken a year or more previously, but it can be accomplished in 3 months today.

The predominant message within this introductory chapter is held in the concept that the drug discovery process involves a rational path of critical steps that a pharmaceutical scientist must think through (*see* Figure 1.3-1). Decisions are made early in a program, often in the conceptual stage, that are forward thinking and with an eye toward the clinical setting and meeting crucial medical needs in the general population. Although these steps appear identical when comparing macromolecular biomolecules and small-molecule paths, many key differences exist. The stepwise nomenclature tends to be consistent, and the two processes can be compared as waves in which there are distinct nodes of intersection yet many distinct divergences between phases. Many of these divergences involve small steps that can be technology driven. For example, the exploratory phases hold similar target identification and validation steps, whereas the subsequent lead identification step may greatly differ in assay development strategies and high-throughput screening with hit-to-lead follow-up (small molecule) versus surrogate selection and characterization (macromolecule). Surrogate antibody characterization (a lead identification function) can often run simultaneously with human antibody generation (a lead optimization function). Even at this early stage, a macromolecule most

likely will be subject to *in vivo* experiments early in the lead identification phase, whereas it may take many months of even preliminary property optimization of a small molecule to probe *in vivo* pharmacology, especially for intracellular targets. As emphasized early in this overview, a great divergence is the one-dimensional versus multidimensional lead optimization dependencies when comparing small molecules and macromolecules and that much discovery speed can be gained given the distinct macromolecule domains. On the side of the drug development process, developing a large or small molecule that satisfies the TPP parameters is similar, and this can be extended to its measurement and performance in clinical trials. Not only do manufacturing processes diverge greatly, but also the ability to make small or incremental process improvements without affecting the composition and integrity of the bulk pharmaceutical product. In a small-molecule manufacturing process, a solvent or reagent can potentially be substituted to improve yield but must have no effect on the overall final product impurity profile, whereas the addition of an alternative feedstock or genetic optimization of a cell culture line can drastically alter a macromolecule's characteristics. In summary, a great appreciation can be gained for the strategic aspects of advancing small-molecule and macromolecular entities and how each step of a rational process is interdependent on the next to efficiently and successfully advance a therapeutic concept to the pharmacy shelves. Considering all aspects of small-molecule and biologics research and development, including the differences in attrition and speed [1], optimal integration of both approaches into the research and development portfolio may be the best strategy for the future.

ACKNOWLEDGMENT

We thank our colleage, Dr. Hans-Jürgen Krause, for very helpful contributions to and discussion of the Formulation and Drug Device sections and Lori Lush, PharmD, for helpful assistance with the manuscript.

1.4.1 INTRODUCTION

From the three major classes of biomolecules including proteins, nucleic acids, and carbohydrates, the carbohydrates entering the constitution of glycans and polysaccharides are, at the moment, the least exploited in biology. The recent development of operating methods for the analysis of carbohydrates and for the synthesis of oligosaccharides support the efforts made to investigate the roles of carbohydrates in biological phenomena [1–4]. Different already identified functions of carbohydrates may be interesting to be integrated within drug delivery systems conferring new properties and opening avenues for innovative developments. In this view, carbohydrates may be used either as a drug due to their own biological activities or as a molecule to design nanoparticles with new functionalities [5–8]. Developing drug delivery systems, the main challenge is to design systems able to carry and target a drug to the diseased organs or cells after administration in the body by the appropriate route [6, 7, 9, 10]. This assumes that the biodistribution of the carrier system is perfectly controlled after *in vivo* administration. In the case of a soluble carrier, this can be achieved by grafting define types of carbohydrate ligands on the polymer backbone [10, 11]. Using colloidal particles like liposomes and polymer nanoparticles, it is now well accepted that their biodistribution is mainly controlled by their surface properties [9, 12–15]. Several carbohydrates and polysaccharides were identified at the surface of cells, bacteria, and viruses as having a key role in biological recognition and signaling events. Therefore, the potential of their use as coating material or as ligands to promote specific recognition between carrier and target cells was carefully considered as a possible way to develop biomimetic drug delivery systems having different functionalities [16–24]. In this chapter, we will summarize the main stages of the development of carbohydrates and polysaccharides as components of interest to be used either as a targeted drug or as a component entering the design of drug delivery systems. The first part of the chapter will focus on the principal milestones that allowed discovery of most of the carbohydrates and polysaccharides known today in terms of their chemical analysis and biological activity investigations. This part will also present status about the chemical synthesis of these compounds. The second part of the chapter will briefly discuss the current state and limitations to the developments of nanoparticle drug carriers. Integration of carbohydrate and polysaccharide developments in the design of drug delivery systems with new functionalities will constitute the third part of the chapter. The fourth and fifth parts will, respectively, review the current research about applications of nanoparticles as delivery systems for biologically active carbohydrates and the use of nanoparticle drug carriers made of polysaccharides for the delivery of fragile bioactive molecules.

1.4.2 CARBOHYDRATE RESEARCH: MAIN STEPS OF DEVELOPMENT AND DISCOVERY OF THEIR FUNCTIONALITIES

Forty years ago, Eylar [25] suggested for the first time that the carbohydrate units found in biologically active glycoproteins could act as a kind of “chemical label” or “chemical passport” to promote specific interactions of glycoproteins with corresponding cell-surface receptors to achieve their transportation across the cell

membrane. However, progress in the understanding of the biological role of glycan moieties included in biological structures was hampered for a long time, because glycans and polysaccharides were much more complex structures to study than were proteins and nucleic acids. Thus, it was only 30 years ago, while full chemical synthesis of peptides was already possible and that of nucleic acid was in its infant age, that various carbohydrate containing compounds came into light as important elements in the number of biological activities [26–30]. For instance, the years 1976 to 1983 were critical in the discovery of the antithrombine binding site of heparin, which now can be used to confer anticlotting and anticomplement activation properties to drug carrier systems [30–32]. The study of lectines isolated from animals that are now known to be involved in many biological recognition molecules involving carbohydrates started to grow rapidly in the 1980s thanks to the development of recombination techniques to produce them [28]. Identification of the role of these molecules in recognition phenomena as well as understanding their functionality are interesting to be able to promote specific recognition between target cells and drug delivery systems achieving drug targeting. It is also noteworthy to point out the discovery of carbohydrates and carbohydrate derivatives that are currently used as major anticancer drugs and antibiotics in clinics [33–35]. Because of the high toxicity of these compounds for the healthy tissues, they are good drug candidates to be incorporated in nanoparticle drug carrier systems improving their specific biodistribution.

For long, progresses in glycobiology were hampered due to technological difficulties in analytical order. The appearance of the high-performance anion–exchange chromatography (HPAEC) in the mid-1990s revolutionized the analytical capacity and considerably improved the accuracy of determining the carbohydrate sequences and arrangements in glycans isolated from glycosylated biological compounds [2, 4]. This was a significant milestone that boosted the resolution of glycan structures and in parallel opened new areas to further investigate their biological activity. The analytical techniques were constantly improved by the subsequent introduction of pulsed amperometry detection (PAD) and more recently by online coupling the HPAEC to mass spectrometry devices and nuclear magnetic resonance (NMR) methods using a nano-probe [3, 4, 36–38]. New methodologies continue to be developed improving performance of the existing analytical methods [39]. The introduction of screening methods using microarray and chip technologies appeared within the last 3 years accelerating discovery and progress toward the understanding of the role of carbohydrates in biology [29, 40, 41].

Research into the biological roles of carbohydrates may be possible because sufficient quantities may be isolated from natural extract. Because of their structural complexity, it is extremely difficult to isolate pure carbohydrates from natural sources. Progress in the analytical chromatographic methods has helped to improve preparative techniques providing purified fractions of defined glycans from various natural extracts [36, 42]. However, the only way to access very pure carbohydrates relies on their chemical or enzymatic synthesis, which also constitutes the more attractive route for the production of the sufficient quantities for biological studies designed to identify biological roles and eventually medicinal interests. The synthesis of polysaccharides and glycans was an important technological challenge. The intensive efforts based on innovative strategies led to major advances, making the synthesis of complex carbohydrates now possible [1, 43–45]. Stereoregular

polysaccharides, including linear, branched, amino, and deoxy polysaccharides, can be synthesized by ring opening polymerization of anhydro-sugar derivatives [1]. The technically extremely difficult synthesis of highly branched carbohydrates was made possible with the development of solid-phase synthesis strategies [44]. Another important milestone was completed thanks to the recent development of an automated oligosaccharide synthesizer leading to accelerated access to many highly branched carbohydrates for identification of their biological function [44]. Even if this methodology provides just enough glycan to study the biological role of the product, this really opens avenues for the identification and creation of important compounds for future biochemical and medicinal applications [44]. For instance, after years of research, many synthetic heparins proposed as anticoagulant drugs can be synthesized on a production scale. They are currently at different stages of clinical development [46]. The chemistry remains complicated, and some synthetic routes that have been scaled up comprised up to 65 steps.

1.4.3 DEVELOPMENT OF NANOPARTICULAR DRUG CARRIERS: CURRENT STATES AND LIMITATIONS

Despite several advances in chemotherapy, the real therapy of cancer and major infections remains a challenge. One problem comes from the nonspecific drug distribution resulting in low tumor or infected tissue concentrations and systemic toxicity. Another problem comes from the lack of stability of drugs in biological media and their incapacity to cross biological barriers. To improve drug concentration in the targeted tissues, several approaches have been suggested, including the association of the drug to carrier systems. A large piece of work has been done using liposomes as carriers, which has led to several marketed formulations so far. For instance, the liposomal formulation of Amphotericin B, which is the leading compound in the treatment of leishmaniasis is today the more efficient treatment against this parasite and other fungal infections [47]. The toxicity of Amphotericin B was reduced by a factor of 50- to 70-fold, which is among the most obvious benefit for the use of this liposome formulation in clinics [48]. The main drawback of liposomes remains the cost of the phospholipids entering their composition. To reduce cost, the biggest challenge is believed to come from polymer nanoparticles. Indeed polymers are a much cheaper material compared with phospholipids, and methods for producing nanoparticles are generally simpler. Other advantages of the polymer systems are their higher stability in biological media especially for the administration of drugs by mucosal routes and upon slight changes in the formulation. Additionally, they should be theoretically tailor-made thanks to the progress in colloid and polymer technology [9, 49]. However, only a couple of polymers are suitable as main components of the polymer nanoparticles designed as drug carrier systems [6, 7, 9]. As for liposomes, polymer nanoparticles were developed as drug carriers to improve the efficacy of the associated drug thanks to a better control of its biodistribution toward the diseased organ or cells and to their faculty to overcome biological barriers [9, 50, 51]. These colloidal particles have demonstrated enhanced efficacy for numerous drugs compared with conventional formulations. Indeed, the biological activity of the drug associated with the carrier is generally improved, whereas the side effects due to their toxicity are reduced thanks to a better control of the biodistribution [52–57]. The improved efficacy can also be explained by a

higher stability of the drug in biological media and ability to overcome biological barriers. However, the main limitation of these systems remains the full control of their biodistribution because they still lack precise targeting specificities. This is the main challenge that remains to be addressed. According to our current knowledge, a better control of the interactions between the drug delivery system and surrounded biological media should improve targeting efficacy as well as promote the occurrence of highly specific interactions. Thus, it was postulated that the control of the biodistribution of drug carriers could be possible by modifying and by adjusting the surface characteristics of the drug delivery systems. The modification of surface properties of drug delivery systems by coating with poly(ethylene glycol) actually rerouted the carrier from a very efficient recognition and uptake by macrophages of the mononuclear phagocyte system (MPS) toward long circulating particles in the blood stream [58, 59]. It is now admitted that the biodistribution of a drug carrier greatly depends on the nonspecific and specific interactions between its exposed surface and the biological components of the surrounded medium found either in blood, on the cell surface, or at the level of biological barriers, i.e., endothelium or mucosa. Thus, efforts are now carried on tailoring the design of the carrier surface [12].

To be used as drug carriers, different drugs should be incorporated into the nanoparticles. Most nanoparticles made of synthetic polymers, including polyesters or polyanhydrides and poly(aminoacids), can incorporate enough lipophilic drugs. However, they are totally inefficient to incorporate hydrophilic molecules such as peptides, proteins, or nucleic acids. These molecules with a high therapeutic potential hardly cross biological barriers. They need to be associated with a drug carrier enhancing their transport across the biological barriers and preserving their biological activity because they are highly un-stable in biological media. This problem could be solved using nanopar-ticles made of poly(alkylcyanoacrylate) [60]. Polysaccharides extracted from natural compound could also be used to formulate new types of drug delivery systems in which macromolecules from biotechnology could be incorporated [6–8, 61, 62].

1.4.4 INTEGRATION OF CARBOHYDRATE IN THE DESIGN OF NANOPARTICLE DRUG CARRIERS WITH NEW FUNCTIONALITIES

As mentioned, the interactions of nanoparticle drug carriers with the surrounded biological environment are key factors controlling the *in vivo* fate of the transported drug. Three levels of interactions may be distinguished, but all will involve surface phenomena between nanoparticle surface and compounds of the surrounding environment. Interactions occurring at the level of a mucosa may be critical to promote the absorption of the drug. They will be discussed in the first paragraph. The interactions taking place in the blood compartment that greatly affect the biodistribution of the carrier due to interactions with blood proteins are considered in the second paragraph. Finally, the more highly specific interactions between drug carrier and cells in the view of targeting and allowing delivery of the drug to precise cells will be considered in the last paragraph of this section. As will be discussed, carbohydrates seem, in all of these cases, as versatile tools to control the interactions between the drug carriers and the biological surrounding media.

1.4.4.1 Carbohydrates to Improve Mucoadhesion of Nanoparticle Drug Carriers

Mucosal routes, especially the oral route, are the preferred methods for the administration of drugs. However, many drugs remain poorly available when they are administered by these routes. Among other reasons, this can be due to low mucosal permeability for the drug, permeability restricted to a region of the gastrointestinal tract, low or very low solubility of the compound that results in a low dissolution rate in the mucosal fluids and in elimination of a fraction of the drug from the alimentary canal prior to absorption, and lack of stability in the gastrointestinal environment, resulting in a degradation of the compound before its absorption (e.g., peptides and oligonucleotides).

To reduce problems of low permeability and low solubility, it was proposed to retain the drug at the surface of the mucosa using bioadhesive formulations increasing the contact time between the drug and the epithelium and in turn chance to the drug to be absorbed. In this aim several authors have suggested to use polysaccharides to design bioadhesive nanoparticle drug delivery carriers. Chitosan obtained from deacetylation of chitin is the most commonly used bioadhesive polysaccharide. At the level of mucosa, chitosan is known to enhance drug absorption thanks to it bioadhesive properties and to its capacity to induce transient opening of the tight junctions without damaging the cells [63, 64]. The bioadhesive properties of chitosan were described for the first time by Lehr et al. [65]. They depend on the molecular weight [66, 67] and on the pH of the surrounded media, which affect the polysaccharide solubility. Chitosan is soluble at pH below 6, and its bioadhesive properties require that the molecule is either soluble or strongly swollen [68]. Thus, to improve the solubility properties of chitosan especially at pH higher than 6 encountered at the level of several mucosa, modified chitosan were synthesized. For instance, the partial substitution of the amino function of chitosan by methyl-5-pyrrolidone led to derivatives enhancing the absorption of drugs at the level of the bucal and vaginal mucosa [68–70]. Enhancement of the bioadhesive properties and of drug absorption was also reported after introduction of thiol groups in the structure of chitosan. In this case, the thiol groups are assumed to form disulfide bonds with the cystein-rich domains of the mucus glycoproteins standing on the gastrointestinal mucosa [71, 72]. Drug carriers that have been coated with chitosan also showed enhanced bioadhesive properties at the level of different mucosa, including the ocular, nasal, gastrointestinal, and pulmonary mucosa [8, 73–76]. However, it is worth pointing out that a simple adsorption of chitosan at the nanoparticle surface is not stable enough to resist desorption when the nanoparticles are in contact with the mucus [77]. Thus, several authors have suggested preparing nanoparticles directly with chitosan obtaining plain chitosan nanoparticles [7, 75] or using copolymers of chitosan and the polymer constituting the nanoparticle, i.e., poly(lactic acid) [61] or poly(alkylcyanoacrylate) [19, 21, 62, 78].

According to Prego et al. [8], the mucoadhesive properties of the carrier and its interaction with the mucus occurring *in vivo* are determinant to provide an efficient transport of the nanodevice carrying the drug across the epithelium, resulting in an increase of the bioavailability. The mucoadhesive properties were shown to depend on the coating material but also on the size of the nanoparticles [8, 79]. Generally, the smallest nanoparticles accumulate more because of a higher

diffusion in the mucus layer compared with bigger particles. However, according to a recent study, Bertholon et al. showed that the conformation of the chitosan chains grafted at the surface of poly(alkylcyanoacrylate) nanoparticles also influenced the bioadhesive properties of the nanoparticles on the intestinal mucosa [21]. Indeed, these authors reported differences in bioadhesion with nanoparticles onto which chitosan was grafted either on a "side-on" conformation or on the "end-on" conformation. Adhesion of the nanoparticles to the intestinal mucus layer can be viewed as a complex process, including the diffusion of the particles in the hydrogel, depending on their size, followed by their interactions with the mucus glycoproteins depending on both the nature of the polysaccharide and its conformation at the nanoparticle surface. It is likely that the molecular interactions played a key role in this latter process. Interestingly these results suggest that the bioadhesive properties of nanoparticulate systems can be modulated by a fine tuning of the surface properties of the particles.

Several other polysaccharides were used to obtain bioadhesive formulations of drugs [80, 81]. Hyaluronic acid, which is applied in ocular surgery to protect the corneal endothelium and to manipulate intraocular tissue is also a remarkable bioadhesive. It was suggested as coating material at the surface of nanoparticles made of poly(epsilon-caprolactone) for the development of bioadhesive ocular formulation of bioactive molecules to increase the retention of the drug at the level of the precorneal zone [82]. The other polysaccharides found in pharmaceutical formulations that may be interesting to use as bioadhesive coated material at the surface of nanoparticle drug carriers are alginate, dextran, starch, and cellulose derivatives, including carboxymethylcellulose and hydroxypropyl cellulose. These polysaccharides have in common high swelling properties in an aqueous environment.

1.4.4.2 Use of Carbohydrates to Control the Fate of Drug Carrier After Intravenous Administration

The fate of nanoparticles administered by the intravenous route is controlled by the interactions between the nanoparticle surface and the serum proteins. In the blood, nanoparticles are normally considered foreign bodies and are rapidly recognized as such by the host defense system. The primary event of the recognition phenomena is basically nonspecific and results in a massive adsorption of serum proteins at the nanoparticle surface [14, 58, 83]. Consequently, the complement system is activated, leading to the labeling of the nanoparticle surface with specific activated proteins of the complement systems. Once the nanoparticles are labeled with activated complement proteins, they are efficiently recognized by macrophages of the mononuclear phagocyte system (MPS) due to the presence of the corresponding receptors at the cell surface. The overall process is so efficient that less than 5 minutes are generally necessary to remove from the blood 80% to 90% of the injected dose of the drug carrier. After these events, the drug and its carrier are found in macrophages of the liver and of the spleen [9, 12, 84–87]. This phenomenom is highly beneficial to target drugs in the liver and spleen but hamper the distribution of the drug toward other biological territories.

Targeting territories, organs, and tumors located outside the MPS organs can be achieved by triggering the host defense systems thanks to the modification

of blood–protein interactions with the nanoparticle surface in order to obtain long circulating nanoparticles. The more general approach consists of grafting poly(ethylene glycol) chains at the nanoparticle surface to reduce both opsonization of the carrier surface by blood proteins and complement activation [14, 15, 58, 88]. An alternative route is based on a biomimetic approach using carbohydrates as material to coat the nanoparticle surface in order to modify interactions with blood proteins [19, 20, 31, 32, 89–92]. The design of biomimetic drug delivery systems using carbohydrate as surface coating material is almost infinite as much of the diversity of carbohydrates appears to be in Mother Nature as exposed at the surface of the eukaryotic cells, bacteria, and viruses [5, 40, 44]. So far, only simple polysaccharides were used to modify the surface properties of nanoparticle drug carriers. The simplest polysaccharide was dextran, which is an alpha-1-6-poly(glucose). Measurements of complement activation given by different dextran-coated nanoparticles provided contradictory results depending on the method of the nanoparticle preparation. Indeed, dextran-coated poly(alkylcyanoacrylate) nanoparticles prepared by redox radical polymerization induced only a low complement activation [19, 20, 31, 32], whereas dextran-coated nanoparticles prepared by other methods induced a strong activation of complement, as does sephadex, which is a reticulated dextran [19, 20, 32, 90, 93, 94]. The contradictory complement activation measured could not be correlated to a marked difference in the interaction of the nanoparticles with blood proteins. Indeed, each type of the nanoparticles showed a proper pattern of blood protein adsorption and no general behavior could be drawn [32]. The hypothesis suggested that explains the results of complement activation is that it may depend on the conformation of the dextran chains at the nanoparticle surface, which can be defined by the method of nanoparticle preparation. This hypothesis is supported by the results of a very recent work that showed that nanoparticles with dextran chains grafted at the nanoparticle surface on the "end-on" conformation are nonactivators when the molecular weight of dextran passes above a certain limit (40,000 g/mol), whereas the nanoparticles on which dextran are arranged on a "side-on" conformation activated complement whatever was the molecular weight of dextran [20]. The effect of the polysaccharide chain conformation was more evident with a series of chitosan-coated nanoparticles. Indeed, nanoparticles with chitosan on the "end-on" conformation were frankly nonactivators, whereas the nanoparticles with chitosan on the "side-on" conformation were strong activators [20]. Although the conformation of the polysaccharide chains at the nanoparticle surface seemed to be a key parameter to control complement activation, several authors showed that the presence of dextran at the nanoparticle surface reduced the adsorption of albumin in favor of a reduction of opsonization phenomena [92, 95]. In terms of biodistribution of the corresponding nanoparticles, the nanoparticles having dextran on the "side-on" conformation were recognized by macrophages of MPS and concentrated in the liver and in the spleen [13], whereas the nanoparticles with dextran on the "end-on" conformation remained in the blood circulation for a longer period [89].

Although chitosan-coated nanoparticles showed contradictory results in complement activation depending on the conformation of the chains at the nanoparticle surface [20], the level of complement activation induced by chitosan was also influenced by the physico-chemical properties of the polysaccharide, including its solubility, degree of deacetylation, and molecular weight [20, 96–98]. Using different

chitosan and chitosan derivatives, nanoparticles with a prolonged circulation time in the blood can be obtained. Additionally, their distribution can be modulated in a certain way because they were found to accumulate in defined tissues outside the MPS [99–104].

In Mother Nature, sialic acids play a key role in the biological mask hiding epitopes at the cell surface, which are immediately recognized by macrophages when the sialic acid is removed from the cell surface [103–107]. The most typical example is given by the erythrocytes, which are rapidly destroyed when sialic acids are removed from their surface [106, 108, 109]. Highly virulent bacteria have also adopted sialic acids as coating material to escape host defense mechanisms [110–112]. Sialic acid, which seems to inhibit complement activation, allows cells and particular material to stay in the blood without being recognized by macrophages [110]. Thus, it was suggested to coat nanoparticles with sialic acids to mask their surface and avoid recognition by macrophages. Two different approaches were followed. At first, the ad-sorption of a sialic acid-rich glycoprotein, orosomucoid, at the surface of poly(alkylcyanoacrylate) nanoparticles reduced opsonization of the nanoparticles and complement activation. However, the orosomucoide that was simply adsorbed at the nanoparticle surface was rapidly displaced from the surface by other serum proteins due to the Vroman effect, and the effect of the sialic acids could be shown on short duration [17, 113]. Second, the nanoparticles coated with sialic acid were obtained from a copolymer of poly(sialic acid) and poly(lactic acid). These nanoparticles coated with a polysialic acid remained in the blood circulation longer than the uncoated nanoparticles after intravenous administration to mice [114]. Poly(sialic acids) have the advantage of being biodegradable, and their catabolic products (i.e., neuraminic acids) are not known to be toxic. Another important advantage of poly(sialic acids) is their T-independent antigens, meaning that they do not induce immunological memory. Because of these properties, poly(sialic acids) are very promising molecules to design biomimetic drug carrier systems with an increased half-life in the blood stream of the drug carrier [16, 115]. The main limitation of the development of such drug carriers so far may be explained by the poor availability of poly(sialic acids), which remain a problem because they are produced by highly pathogenic bacteria strengths at a very high cost.

The other bioactive polysaccharide that seemed interesting to be used to produce surface-modified nanoparticles reducing their recognition by the host defense was heparin. Heparin is used as a drug for its anticoagulation properties. Additionally, it is an inhibitor of the complement activation phenomenon [116–118]. It was demonstrated that heparin-coated nanoparticles did not activate the complement system [19, 31, 32] and remained in the blood stream for a longer time compared with nanoparticles, which do not show heparin on the nanoparticle surface [89]. Other polysaccharides extracted from mushrooms were found to inhibit the activation process of the complement. They could be alternative polysaccharides to produce nanoparticles with a reduced capacity to activate the complement, such as heparin [119].

According to the current experiences, several polysaccharides can be used to modulate the interactions of nanoparticle drug carriers, with blood proteins modifying their blood clearance and consequently their biodistribution. Two categories of polysaccharides giving nanoparticles an ability to escape recognition from macrophages of the MPS can be identified. The first category, including heparin and sialic

acids, specifically interact with serum protein according to a well-defined mechanism, thanks to their specific biological activity being inhibitors of the complement activation phenomenom. The polysaccharide of the other category, including dextran, interacts with serum protein through nonspecific interactions. In addition to the specific and nonspecific interactions with blood proteins, it was clearly demonstrated that the conformation of the chains grafted at the nanoparticle surface is one key parameter that controls the complement activation phenomena and the opsonization of the nanoparticle surface. The nature of the polysaccharide and the molecular weight took on the second level of importance [20].

1.4.4.3 Carbohydrates and Drug Carrier Targeting Perspectives

Colloidal carriers have proved to be interesting to deliver drugs by the intravenous route because of their potential to improve the therapeutic index of the carried drug while reducing their side effects. Although with the current systems available it can be possible to enhance accumulation of the drug in diseased tissue, especially in tumors, the interactions of the carriers with diseased cells and their uptake remain insufficient. The main strategy that was proposed to further enhance drug delivery and retention at the level of diseased cells is based on the active targeting of the drug [12, 120–122]. This supposes that drugs reached target cells thanks to a highly specific biodistribution of the carrier. Our experience with drug carriers suggests that such a degree of specificity will only be obtained if the drug carrier can recognize the target cells through specific interactions.

One way to promote recognition between drug carriers and target cells is to attach ligands at the carrier surface that can bind specifically to target cells [12, 121, 122]. For this purpose, more or less complex carbohydrates can be used as ligands of endogenous receptors for carbohydrates known as lectins at the cell surfaces. Lectines are universally found in the microbial world, on vegetal and animal cells [5, 28, 123]. They can bind various types of carbohydrates from simple monosaccharides to oligo- or polysaccharides of complex structures with a very high specificity of recognition resulting in strong interactions. The binding is a very fast process, and the recognition between the carbohydrate and the corresponding lectin can occur whether the carbohydrate is free or bound on a macromolecule or on the surface of cells and of drug carriers [123, 124]. So far, the majority of the work done in the field of active targeting was performed with liposomes and soluble polymers. Currently, only a few studies were carried out on nanoparticles [12, 121, 125]. Microbial and vegetal lectins were bound to drug carriers as targeting moiety to find complementary carbohydrate epitopes at the surface of target cells [126–128]. However, with the recent progress in glycobiology, it seems that a better option would consist in grafting the carbohydrates on the drug carrier instead of lectins, which often lose activity during the grafting process. Another advantage of using carbohydrates as the targeting moieties is that the drug carrier would be targeted toward cell receptors with expression levels that are subjected to dramatic modifications upon physiological conditions of the cells. For instance, in several cancer cells, some receptors are specifically over-expressed, whereas other are downregulated and almost disappear from the cell surface. Thus, it seems better to use the ligand receptor, i.e., carbohydrate, as the targeted moiety attached on the drug carrier to take advantage of differences in the level of receptor expression

in the targeting strategy. This method, which was applied with folic acid, actually showed high targeting potential [129]. Additionally, it would probably be easier to find universal methods for grafting various types of carbohydrate moiety on nanoparticle surface in comparison with the coupling methods of proteins, which need to be finely adjusted for each protein receptor to preserve the functionality of their active site [44].

Many endogenous lectins in animals might serve as target receptors for drug carriers exhibiting complementary carbohydrates at the surface. Examples of animal lectins and principal characteristics, locations, and specificities are given in Table 1.4-1, whereas Table 1.4-2 summarizes variations of the level of expression of lectins in several diseases that were already identified and reported in the literature.

This last table may be especially useful for identifing over-expressed lectins on diseased cells and may be used as a target to direct drug delivery carriers, bearing the corresponding carbohydrate ligand specifically toward them. Such a targeting strategy was successful using soluble drug carriers [126, 137, 141, 142], and in the case of targeting DNA/polymer complexes [130, 143–147] bearing simple carbohydrate or polysaccharides. Most of the work done so far with nanoparticles included mono- and di-saccharides as the targeting moiety. Lectins can recognize galactose and mannose residues after chemical grafting at the surface of polymer nanoparticles [148, 149]. Galactose was used to target paclitaxel-loaded nanoparticles toward hepatic cells. The lectins of the hepatic cells specifically recognized the galactose residues at the surface of the nanoparticles, improving the targeting of the drug in these cells. Thus, the nanoparticles were found to be more toxic toward the cells expressing the lectin at the surface compared with cells devoid of the corresponding lectin [147]. It also seems that lactose bearing nanoparticles that are recognized by asialoglycoprotein receptors of hepatic cells of mice are internalized by endocytosis [148]. A carbohydrate of Lewis was suggested as targeting moiety to target poly(lactide-co-glycolide) nanoparticles toward cells expressing E selectins on endothelial cells or in inflammatory sites. It was found that, for this more complex carbohydrate corresponding to an oligosaccharide, the affinity of the E-selectins for the Lewis carbohydrate exposed at the nano-particle surface depended on the density of grafting [121].

According to these data, targeting strategies that involve carbohydrates are principally directed toward cell receptors involved in the mechanisms of cell regulation and communication either between cells or with the surrounding medium. They are based on specific interactions with high affinity between the ligand and the corresponding receptor. So far, they have been applied with simple carbohydrates, including monosaccharides, di-saccharides, and some Lewis carbohydrates. It provided more than satisfactory results regarding the level of targeting specificity as evaluated *in vitro* using relevant cell models. Only a few studies that went over the *in vitro* stage were performed with liposomes and soluble drug carriers, providing extremely convincing perspectives [122, 141, 152]. There is no doubt that similar targeting efficiency may be obtained with success using nanoparticles. It can also be expected that current investigations aiming to identify structures and the biological functionalities of carbohydrates at a large scale will contribute to amplify our knowledge of cell communication and therefore highlight new targets and target carbohydrate-based materials [5, 35, 40, 44, 153]. This promises very exciting

TABLE 1.4-1. Principal Characteristics of Some Animal Lectins

Class	Subclass	General Properties	Localization	Specific Ligand	Non-Specific Ligand	Ref.
C—Lectins Calcium dependent	Endocytic receptors	Asialoglycoprotein receptors	Hepatocyte	Ending β D galactose Ending N Acetylgalactosamine		[120, 130]
		Involved in the clearance of desialylated proteins	Liver endothelial cells	Ending N Acetylgalactosamine		
			Kuppfer cells	Ending N Acetylgalactosamine		
			Macrophages	Mannose		[131, 132]
			Parenchymal liver cells	Arabinogalactane Ending Galactose	Dextran	
			Non-parenchymal liver cells	Pullulan Manan	Dextran Pullulan Arabinogalactan	[133]
	Selectins	Transmembrane glycoproteins involved in cell traffic to injury and inflammation sites	Platelets (P selectin) + endothelial cells	Heparin		[121, 125]
			Endothelial cells (E selectin)			[121, 125, 134]
			Leukocyte (L selectin)	Sulfated and sialylated ligands Heparin		[132, 134]
	Collectins	Involved in innate immune phenomena		Saccharides on pathogens or allergens		[132]

C—Lectins Calcium dependent	Proteoglycans	Involved in regulation mechanisms of cell growth, differentiation, and lipid metabolism	*Hyaluronate receptor:* CD44: hematopoietic cells Fibroblast	Hyaluronic acid and sodium salts		[135–138]
			RHAMM: Fibroblast Smooth muscle cells Macrophages Lymphocytes ICMA 1: Leukocytes Macrophages			[139]
			Non hyaluronate receptors:	Fructose, Galactose		[132]
S-Lectins Calcium independent	Galectins 1	Cell adhesion and proliferation, regulation of immune infections	Skeletal muscle	B Galactoside Glucose		[132, 140]
	Galectins 3	Allergy, inflammatory process	Eosinophils Neutrophils Macrophages Epithelial cells	β Galactoside Glucose		[132–140]

TABLE 1.4-2. Modification of Expression Level of Different Lectins in Several Pathologies

Pathologies	Over-Expressed Lectins	Under-Expressed Lectins	Ref.
Cancer	P Selectins in plasma Hyaluronate receptor CD44 and RHAMM Galectins		[121, 125, 140]
Metastasis	E Selectins Hyaluronate receptor CD44 and RHAMM		[132] [135–138]
Colon cancer	Galectins 1 et 3	Galectin 8	[126]
Meningeal leukaemia	L Selectins		[121]
Malignant B-cells	L Selectins		[121]
Angiogenesis	E Selectins		[132]
Connective tissue disease	P Selectins in plasma		[121, 125]
Rheumatoid arthritis	P Selectins in plasma E Selectins		[121, 125]
Asthma, allergy	P Selectins in plasma E Selectins	L Selectins	[121, 125]
Multiple sclerosis	L Selectins		[121]
Kawasaki disease	E Selectins	L Selectins	[121]
Guillain—Barre syndrome	E Selectins		[121]
Intestine disease	P Selectins in plasma		[121, 125]
Sever infection (malaria)	P Selectins in plasma E Selectins		[121, 125]
Neonatal bacterial infection		L Selectins	[121]
HIV	L Selectins		[121]

Cardiopulmonary bypass surgery		L Selectins	[121]

developments in the future. However, as stressed by Nobs et al., one has to keep in mind that the ability to achieve targeting *in vivo* depends directly on whether the target is accessible from the vascular compartment [12]. In the first case, particles bearing targeting moiety and having long circulating properties have a high probability to reach the target cells. On the contrary, when the target is extravascular, for instance, in solid tumors, penetration of the carrier in the tumor tissue is more difficult because it needs to extravasate. In this case, the size of carriers needs also to be adjusted so that they can cross the vessel endothelial through the pores of the local discontinuous tumor microvasculature, which may vary between 100 and 780 nm. Another requirement would probably concern the orientation of the carbohydrate moiety at the nanoparticle surface. Indeed, biological recognition systems are so sensitive that they are, for example, capable of differentiating small changes in the conformation of epitopes at the surface of pathogens.

1.4.5 ENHANCEMENT OF CARBOHYDRATE THERAPEUTIC ACTIVITY BY ASSOCIATION WITH NANOPARTICLE DELIVERY SYSTEMS

Research to understand biological functions of carbohydrates is currently extremely active providing new data almost everyday. The literature is growing exponentially in this very fast moving area. The purpose of this chapter was not to review all the different biological activity known for carbohydrates today but was to focus on carbohydrates whose biological activity is interesting for therapeutic purposes and whose therapeutic efficacy may be improved by association with a nanoparticle drug carrier.

1.4.5.1 Anti-Infectious Agents

The emergence of antibiotic resistant strengths of bacteria, parasites, fungus viruses, and new pathogens are very demanding for the discovery of new anti-infectious agents. If the discovery of new molecules is undoubtedly the leading strategy in finding effective treatments, all active molecules will need to reach sites of infections where pathogens are located at sufficient concentration. Several efficient carbohydrate antibiotics were extracted from various strengths of *Streptomyces*. They are simple aminoglycoside molecules known as streptomycins, including neomycin, gentamicin, or amikacin. Other recently discovered carbohydrate antibiotics, including the family of the orthosomycins, are more complex molecules. These carbohydrate antibiotics are very attractive because they are efficient against pathogen bacteria, including those resistant to antibiotics used as a last resort (penicillin or vancomycin). Their interest is so huge that several methods for their synthesis were already suggested [154–156]. However, they are generally very toxic for healthy tissues limiting the maximal dose of antibiotic that can be administered in patients and consequently the efficacy of treatment. In general, the efficacy of antibiotics can be considerably increased when they are associated with drug carriers thanks to a reduction of the toxicity and a higher accumulation in the infected cells that, in many infections, are cells of the mononuclear phagocytes system. The improvement of the safety profile of the targeted drug allowed administration of higher doses of the antibiotic when requested to promote treatment efficacy [48, 157]. In other cases, the therapeutic index of the antibiotic was markedly increased by a factor ranging from 6 to up to 120; thus, the dose of antibiotic required to kill infectious agents can be considerably reduced [158–164]. Complete sterilization of organs can be obtained with the antibiotic targeted with nanoparticles, whereas the corresponding liposomal formulation can not completely sterilized the organs in the same experimental condition [165].

Currently, there is only one formulation of Amikacin in liposomes under clinical trials for treatment of tuberculosis. The antibiotic was found to be twofold to sixfold more active than the free drug in an acute experimental model of murine tuberculosis in which bacteria are located in macrophages. The count of viable bacteria found in the liver and spleen was reduced by a factor of 3-$\log_{10}$ compared with the untreated mice [158]. However, in human, this formulation was not as active as expected. To explain the disappointed results obtained, it was suggested that the liposomes could target the antibiotics in the macrophages but this was not enough to reach extracellular bacilli, which are clustered in cavity caseum in the human

infection and can be responsible for reinfection. It was suggested that these residual bacteria may be reached using drug carriers with long circulating properties.

So far, the more advanced studies on the targeting of antibiotics that reach the clinic stages were performed with liposomes. The only formulation marketed so far, AmBisome (Gilead, Foster City, CA), is the more efficient treatment against leishmaniasis and other fungal infections [47]. This demonstrates the high potential of targeted formulations of antibiotics to challenge devastating pathogens with toxic antibiotics for healthy tissue provided that they are targeted to the infected cells. It may be expected that research will continue considering targeting strategies of the most interesting carbohydrate antibiotics to improve the efficacy of anti-infectious treatments. In this view, it will also be interesting to pay attention to nanoparticle formulations that seemed more efficient than liposomes when they were tested in the same conditions probably because of their higher stability in the blood compartment *in vivo* [157, 161].

Some polysaccharides showed either antibacterial and antifungal activities or antiviral activity. For instance, the antibacterial and antifungal activity of chitosan was studied for a long time both *in vitro* and *in vivo*. They are used to control bacterial infections during the wound healing process [166]. The activity of chitosan against pathogens is maximal at acidic pH [166, 167]. The degree of acetylation has no influence on the activity, but high-molecular-weight chitosan was reported to be active against the Gram-negative bacteria *Escherichia coli* [168]. Depending on the authors, either high- or low-molecular-weight chitosan were reported to be active on the Gram-positive bacteria *Staphylococcus aureus* [168, 169]. To explain activity of chitosan, it is assumed that high-molecular-weight chitosan may form a film around the bacterial preventing the exchange of nutriment, whereas low-molecular-weight chitosan may enter bacteria cells to disturb metabolism [168]. Other mechanisms were suggested such as chelation of metal ions required for the synthesis of the bacterial toxin or interaction with cell membrane components inducing agglutination of bacteria or increasing of the permeability of the cell membrane [167, 170]. Chemically modified derivatives of chitosan such as diethy–methyl chitosane are more active than chitosan [171]. Chitosan has not yet been used in a targeted formulation for *in vivo* application. However, it was associated at the surface of nanoparticles to obtain fabrics with antibacterial activity.

Finally, antiviral activities were reported for polysaccharides bearing sulfonate groups. Most studies considered either the activity against the human herpes virus simplex 1 and 2 or against the Human Immunodeficiency Virus (HIV). Generally, the antiviral activity depended on the molecular weight, the amount and the distribution of the sulfonate groups, and the conformation and flexibility of the polysaccharide chains [172]. It was suggested that the anti-HIV activity can result from electrostatic interactions occurring between the negatively charged sulfonate groups of the polysaccharide and the positively charged amino-groups of the glycoprotein GP120 of the virus envelope [170]. Polysaccharides with antiviral activity can be obtained by grafting sulfonate or sulfamide groups [172, 174]. Modified dextranes containing carboxymethyl benzylamine and carboxylmethyl benzylaline sulfonates groups showed anti-HIV activity [175], whereas the anti-herpes virus activity was described for carraghennan corresponding to sulfated polygalactanes extracted from a red algae [172]. More interestingly, a sulphated polysaccharide extracted from the algae *Caulerpa racemosa* is active against strengths of the

herpes virus resistant toward acyclovir, which is one of the leading antiviral compound used in clinics [176]. These polysaccharides showing antiviral activity may be interesting compounds to target against infected cells.

1.4.5.2 Anticancer Activity

Several small carbohydrates derivatives showed anticancer activity and are used in clinics as antitumoral drugs [33–35]. Pharmacologically active concentrations of such an anticancer drug in the tumor tissue are often reached at the expense of massive contamination of the rest of the body. As it was discussed with antibiotics, this poor specificity creates a toxicological problem that represents a serious obstacle to effective antitumor therapy. Another obstacle to their efficient delivery is the occurrence of multidrug resistance (MDR), which may appear either as a lack of tumor size reduction or as a clinical relapse after an initial positive response to the tumor tissue; it can be either directly linked to specific mechanisms developed by the tumor cells or connected to the physiology of the tumor tissue, including a poor vasculature and unsuitable physico-chemical conditions [177]. Outside the tumor tissue, the resistance to chemotherapy can be due to the more general problem of the distribution of a drug relative to its targeted tissue [15]. To overcome drug resistance, many attempts have been made using strategies that consider the more general problem of the control of the drug biodistribution either at the cellular level or at the tissue level [178, 179]. These reasons make small carbohydrate antitumoral drugs relevant candidates to be formulated in drug delivery systems allowing their targeting in tumors as it was already demonstrated with the anthracyclin doxorubicin [50, 180–183].

Antitumor activity was also reported for several polysaccharides [35]. Nanoparticles made of chitosan either loaded with copper or unloaded showed a higher cytotoxicity against tumoral cells, whereas their cytotoxicity remained low toward healthy cells of human liver L-02. The antitumoral efficacy depended on the nanoparticle diameter being the highest with the smaller nanoparticles (40 nm) [184]. Heparin showed interesting antitumoral activity especially when it formed a complex with poly(beta-aminoesters), a positively charged polymer, which enhanced the intracellular penetration of heparin by endocytosis into cancer cells. The mechanism of the anticancer activity of heparin was explained by an induction of apoptosis in cells in which the polysaccharide was internalized. The specificity of the activity against cancer cells was explained by a favorable competition of the endocytosis toward these cells compared with the lower endocytosis activity of healthy cells. However, it may be suggested that the specificity of the delivery may further be increased by a specific delivery of the conjugate at the level of the tumor [185, 186]. Many other carbohydrates and polysaccharides have recently been isolated showing antitumoral activity. The characterization of their structure and mechanism of action are still not fully elucidated, and this is part of a very active field of investigation. Among the very recently isolated compounds showing an antitumoral activity, several were extracted from plants, mushrooms, and microorganisms [143, 187–191] or were collected from their culture medium [192]. It was shown that some extracted polysaccharides may interact with the host defense mechanisms to induce a production of interleukin-2, which in turn can stimulate either cytotoxic T lymphocytes, Natural Killer lymphocytes, or the production of an

antibody against tumoral cells [184]. Another hypothesis suggested that the polysaccharides can stimulate macrophages resulted in a production of nitrogen oxide (NO) and of tumor necrosis factor-alpha (TNF-α) [143, 187, 192–194]. A direct activity against tumoral cells was also assumed [188, 189]. Finally, certain active compounds may act on the angiogenesis reducing the formation of neovessels required for the irrigation of the tumor tissue [190, 191].

1.4.5.3 Control of Vascular Smooth Muscle Cell Proliferation

Several sulfonated polysaccharides showed an ability to control proliferation of vascular smooth muscle cells. Certain compounds may act on the angiogenesis reducing the formation of neovessels required for the irrigation of tumor tissues [190, 191]. They can contribute to reduce tumor size growth. Others can inhibit the proliferation of the vascular smooth muscle cells on a damaged artery to prevent and control artherosclerosis [195]. The inhibitor activity of the polysaccharides seemed to increase with their molecular weight because it is assumed that they are better internalized by cells. Among sulfonated polysaccharides, fucan showed a higher activity compared with heparin [196, 197]. With modified dextran, the inhibition of cell growth depended on the degree of substitution by sulfonate groups and on the presence of benzylamide groups. The production of collagen by the vascular smooth muscle cells was influenced by modified dextran and heparin [198]. Complexes among sulfonated polysaccharides, such as heparin, hyaluronate, and chondroitine sulphate with chitosan, were also reported to control proliferation of vascular smooth muscle cells [199].

Sulfonated polysaccharides present different biological activities. To take advantage of their antiproliferative activity toward vascular smooth muscle cells, it will be necessary to associate the polysaccharides with targeted drug carriers such as nanoparticles. The nanoparticles may also enhance the cellular endocytosis of the polysaccharides to further promote its antiproliferative activity on vascular cells.

1.4.5.4 Activity on the Immune System

Many antigens located at the surface of pathogens show more or less complex carbohydrate epitopes. The immune response induced by these antigens results in the production of antibodies, which is relevant in the aim of vaccination [200–203]. Thus, a few vaccines were developed using polysaccharide antigens against meningitis [203, 204], pneumonia [202], and against *Staphylococcus aureus*, which is responsible for nocosomial infections [201]. Usually, an efficient vaccine requires formulation of the antigen with an adjuvant. The more recent formulation strategy that was followed for vaccine development was based on the design of antigen presenting devices using nanotechnology [205–207]. Systems proposed so far are, on the one hand, derived from the liposome technology based on phospholipid bilayer reconstitution with incorporation of antigenic protein or glycoprotein, i.e., virosomes [205, 206], and, from the other hand, on the reconstitution of empty viral capside with viral recombinant proteins, i.e., virus like particles [207]. Finally, the immune stimulating complex (ISCOM) corresponds to a nanosized aggregate (40 nm in diameter) of saponin, lipids, and antigen held together by hydrophobic interactions occurring among the three components [208]. These systems formed spontaneously upon self-molecular assembly mechanisms. They were mainly

developed as vaccines against viral infections and are mimicking viruses showing the corresponding antigenic epitopes at the surface. Although they are efficient for parenteral vaccinations, their application in mucosal vaccines is subjected to controversy because of possible stability problems in the biological environment of mucosa. Thus, there is a need for development of antigen presenting systems for bacterial antigens including those of a polysaccharide nature and for antigen presenting devices stable enough in biological media encountered at the level of mucosa to develop mucosal vaccination. Several types of polymer nanoparticles were proposed as carriers for antigens to be used as vaccine adjuvants [209, 210]. In general, in these systems, the antigen is mostly encapsulated within the nanoparticles and is not "visible" from the outside of the carrier as it is the case of systems obtained by self-assembly molecules, i.e., in virosomes and virus-like particles. Polysaccharide-coated nanoparticles would be more suitable as possible antigen presenting devices. To this purpose, nanoparticles were specifically designed to exhibit polysaccharides at the nanoparticle surface and can easily be obtained with various polysaccharides [211]. Their versatility should offer interesting developments for new vaccines as a polysaccharide antigen presenting device.

Although carbohydrate antigens were first described a long time ago, their interactions with the immune system are not limited to the production of antibodies in the frame of vaccination. Indeed, some polysaccharide can modulate the immune system activity in a specific manner. For instance, several polysaccharides interact with interleukin 10 (IL-10) [212]. Human IL-10 is known to stimulate CD16 and CD64 receptor expression on the monocyte and macrophage population within peripheral blood mononuclear cells. Soluble heparin, heparan sulfate, chondroitin sulfate, and dermatan sulfate inhibit the human IL-10-induced expression of CD16 and CD64 in a concentration-dependent manner. The antagonistic effect of heparin on human IL-10 activity depends on N-sulfation, the de-N-sulfated heparin had little or no inhibitory effect on the IL-10- induced expression of CD16, and the effect of de-O-sulfated heparin was comparable with that of unmodified heparin. Furthermore, the inhibition of cell-bound proteoglycan sulfation reduced the human IL-10-mediated expression of CD16 molecules on monocytes and macrophages. Taken together, these findings support the hypothesis that soluble and cell-surface glucosaminoglycans and, in particular, their sulfate groups are important in binding and modulation of human IL-10 activity and, therefore, promote or inhibit several pathways of the immune system. It may be suggested that these molecules grafted at the surface of a polymer nanoparticles may regulate the expression of the receptors at the cell surface modifying the immune system response in a very definitive and precise manner.

Small oligosaccharides can inhibit immune response by reducing production of oxidative species in immune cells. These components may be interesting to control the inflammatory process and for treatment of autoimmune diseases. Activity depended on both length and conformation of the oligosaccharides. It seemed that oligosaccharides longer than six residues and adopting a helical conformation enhanced interactions with immune system components [213]. The immunomodulation properties shown by such oligosaccharides can be combined with anti-inflammatory properties of other polysaccharides extracted from *Costus spicatus* [214]. Although several oligosaccharides can inhibit immune response, others stimulate the immune system. Polysaccharides extracted from *Lycium barabrum*

promoted expression of IL-2, TNF-alpha, in the peripheral mononuclear cells in human [215]. Those extracted from *Discirea opposita* induced proliferation of T lymphocytes [216]. It was suggested that stimulation of macrophages resulted from an interaction occurring between the n-acetylglucosamine groups of the oligosaccharides with the mannose calcium-independent receptors of the macrophages [217, 218].

Presenting under the form of nanoparticles, these polysaccharides may be better targeted toward macrophages and monocytes to focus the activity of the polysaccharide in macrophages and to avoid reaching other cells that may be affected by unspecific action on metabolism or physiology. Indeed, it will be very important to target precisely polysaccharides like heparin because it has other biological activity. The various activities found for polysaccharides on the immune system may be used to finely tune the activity of the very complex defense system of the host. This could lead to the emergence of new therapeutic strategies, provided the polysaccharides or the oligosaccharides will be precisely targeted against the right cells of the immune systems.

1.4.5.5 Control of Blood Coagulation and Complement Activation

Polysaccharides and oligosaccharides may induce or inhibit blood coagulation depending on their structure. Chitosan and polysaccharides extracted from the Chinese laquer showed biological activity promoting the blood coagulation [173, 219]. In general, negatively charged polysaccharides, including sulphate, sulfonate, carboxylic, and sulphonamide groups, show an opposite activity having anticoagulant properties. Heparin, which is used in clinics and for storage of blood in the blood banks, is for sure the more generally known natural anticoagulant agent [134, 220]. For the other polysaccharides, including sulphated and carboxylated derivatives of dextran, galactomannan, pullulan, and chitosan, it was shown that the amount of functional groups, their distribution along the chain, and the molecular weight of the polysaccharide chains are all parameters that influence the anticoagulant activity of the polysaccharide [174, 220–226]. In clinics, the main problem encountered with treatments based on the use of heparin is the rapid elimination of the polysaccharides from the blood stream. Long circulating formulations of heparin with longer biological and therapeutic efficacy may consist of heparin associated with long circulating drug carriers. It was reported that some nanoparticles coated with heparin displayed long circulating properties and that the anticoagulant activity of the heparin was preserved after grafting on the nanoparticle surface, making these nanoparticles interesting as a potential long-acting anticoagulant agent [19, 89]. Heparin that is used in clinics must be administered via the parenteral route, which is expensive, inconvenient, unsafe, and limits use by outpatients. The development of an oral form of heparin is more than warranted because the oral route remains the preferable route of administration of drugs for patient. It is also the safer and less-expensive route for the administration of drugs so far. However, heparin is a polyanionic macromolecule and is unstable under acidic conditions of the stomach, thus exhibiting poor oral bioavailability [227]. Nanoparticles were found to enhance absorption of hydrophilic macromolecules across the intestinal epithelium [51]. They seemed to be an interesting alternative for the development of an oral formulation of heparin to promote its bioavailability by this challenging route of administration.

1.4.6 NANOPARTICLE DRUG CARRIERS MADE OF CARBOHYDRATES FOR THE DELIVERY OF FRAGILE MOLECULES

Among the different delivery approaches explored so far to deliver complex molecules such as peptides, proteins, and nucleic acids by mucosal routes, those based on the use of polysaccharide nanoparticles were found to be interesting alternatives toward this ambitious goal thanks to physico-chemical and biopharmaceutical properties of these polymers [6–8, 51]. Indeed, the mucosal delivery of these molecules is very challenging, and despite their increasing market value, their clinical use was hampered due to their poor natural transport across biological barriers and their extremely rapid degradation in biological media. Elaboration of the polysaccharide nanoparticles requires neither an organic solvent nor a powerful homogenization procedure, possibly damaging macromolecular drug activity [75, 228]. This is an advantage regarding all other preparation methods of nanoparticles. Indeed, the mild conditions used to prepare polysaccharide nanoparticles suits with those required to preserve the biological activity of peptides, proteins, and nucleic acids in the nanoparticle formulations [9]. So far, nanoparticles made of chitosan have opened promising alternatives for the delivery of peptides, proteins, and nucleic acids by the mucosal route, including oral and nasal administration and for topical delivery of drugs in the eye [229–231]. The system that is stable in the mucosal environment, including in the harsh conditions of the gastrointestinal tract, can interact with the negatively charged glycoproteins of the mucus, which cover the epithelium retaining the nanoparticles on the mucosa surface. This retention effect due to the bioadhesive properties of chitosan to mucus increases the chance for the drug to be absorbed. The drug-loaded nanoparticles either made of chitosan or bearing a chitosan coating enhanced drug penetration and absorption after administration by different mucosal routes. For instance, the oral absorption of salmon calcitonin was improved when it was associated with chitosan nanoparticles. Interestingly, this system elicited long-lasting hypocalcemia levels, whereas calcitonin emulsions used as control led only to a negligible response [8]. To explain the effect, it was suggested that the nanosystems were able to enter the epithelia and provided a continuous delivery of the peptide to the blood stream [8, 232, 233]. Insulin-loaded chitosan nanoparticles also improved the delivery of insulin by the nasal route [234]. This formulation may be interesting for applications requiring a rapid supply of insulin in the blood. Indeed, the hormone is absorbed in about 30 minutes, but the duration of the effect was quite short, lasting for 1.5 to 2 hours.

Chitosan nanoparticles as well as chitosan-coated nanoparticles were also found interesting for the delivery of antigens to the Nasal Associated Lymphoid tissue. The results indicated that the nanoparticles could facilitate the transport of the associated antigen across the nasal epithelium leading to an efficient antigen presentation to the immune system. This elicited both an IgA and an IgG response increasing over time. For the immune response, it was suggested that not only the size and surface properties of the nanoparticles may influence the immune response but also the polymer composition and the structural architecture of the nanosystems, which were found critical for the optimization of such antigen carriers [210]. For the delivery of antigen by the oral route, it has very recently been proposed to coat chitosan nanoparticles with alginate in order to prevent a burst released of the antigen in the intestinal medium and to further improve the stability of the chitosan nanoparticles in this very aggressive medium [235].

Chitosan nanoparticles and chitosan-coated nanoparticles showed interesting bioadhesiveness on the cornea and good ocular tolerance. Their potential for the delivery of drugs at the ocular level was investigated. Both systems showed suitable delivery properties to improve topical administration of drugs at the level of the ocular mucosa [231]. Chitosan-coated nanoparticles, which are very versatile regarding their drug-loading capacity and release properties, increased the drug levels in cornea and aqueous humor to a significantly greater extent compared with the commercial drug preparation or the drug-loaded uncoated nanoparticles. These nanoparticles were clearly able to enhance transportation of the drug across the cornea to reach the inner part of the eye. In contrast, chitosan nanoparticles accumulated into the corneal and conjunctival epithelia, where an increased concentration of drugs can be maintained for a prolonged duration. Initial experiments have indicated the adequate tolerance and low toxicity of these ocular drug carriers [73].

Several polysaccharides can form a complex with nucleic acids. This property was exploited to formulate DNA loaded nanoparticles to deliver genes and antisens oligonucleotides *in vivo*. Most polysaccharide-based carriers were obtained from chitosan and alginate [7, 236]. *In vitro* expression of gene transfected into cells using chitosan nanoparticles reached a similar level than the expression level obtained with reference transfection agents, including Lipofectin (Invitrogen, Cergy-Pontoise, France) and Surperfect (Qiagen S.A., Coutaboef, France) [237]. The nanoparticles presented high encapsulation efficiency and good protection of DNA from DNase digestion [238]. To further improve the transfection properties of chitosan nanoparticles and enhance the specificity of the carrier toward the target cells, Manssouri et al. suggested to attach folic acid residues to the nanoparticle surface [239]. Nanoparticles made of polyesters or silica coated with chitosan or modified chitosan may also serve as carriers for DNA plasmids or for antisense oligonucleotides [7, 62, 240–243]. In these nanoparticles, the nucleic acid is adsorbed onto the carrier surface thanks to the formation of a polyion complex with the polycationic polysaccharide standing at the nanoparticle surface. Another system made of alginate nanoparticles was reported to associate antisense oligonucleotides [244]. The stability of the associated oligonucleotides in the presence of serum was considerably improved, indicating that the carrier system may be suitable for the *in vivo* delivery of antisense oligonucleotides. The main objective of gene therapy is to obtain successful *in vivo* transfer of the genetic material to the targeted tissue. However, the growing potential of gene therapy will not achieve this goal until the issue of gene delivery has been resolved [245]. Naked DNA cannot be delivered efficiently. Consequently, good gene delivery formulations are needed requiring good encapsulation efficiency of DNA, protection from degradation, and specific targeting to desired cells. The optimal system is still not found. The polysaccharide nanoparticles presenting so far good complexing and transfection efficiency are interesting potential systems. It may be expected that research on these systems will continue to grow and expand in the close future.

Polyanionic polysaccharides including heparin were shown to interact strongly with hemoglobin preserving its functionality as oxygen carrier [246]. This was exploited to load functional hemoglobin on heparin-coated nanoparticles to be used as a possible oxygen carrier for *in vivo* applications [247]. The nanoparticles having a diameter of 80 nm showed the highest hemoglobin-loaded capacity compared with other carrier systems. Indeed, they can associate up to 40-mg

hemoglobin per gram of nanoparticles, whereas other nanoparticles showed one third of this loading capacity [247, 248]. The functionality of hemoglobin standing in the heparin corona at the nanoparticle surface was preserved as well as the anticoagulant activity of heparin. This system in which a drug may additionally be incorporated in the polymer core can constitute a new generation of multifunctional drug delivery system.

1.4.7 CONCLUSION

In the recent years, there has been a resurgence of interest in the biological role of carbohydrates. Active research that started a couple of years ago already highlighted the many biological roles and the diverse functions of carbohydrates in physiological and diseased processes. Several are useful for application as powerful drugs providing they are specifically delivered to the diseased cells. Their combination with nanoparticle drug carriers may be required improving their efficacy and specificity at the target site. From another point of view, several polysaccharides seemed to be interesting constituents of a drug carrier having remarkable mucoadhesive properties and promoting drug delivery by mucosal routes. The wide applications of carbohydrates in the design of drug delivery systems are illustrated in Figure 1.4-1.

Carbohydrate-based nanoparticles seemed to be well tolerated so far. However, full toxicological studies have not been performed yet and safety of the formulated

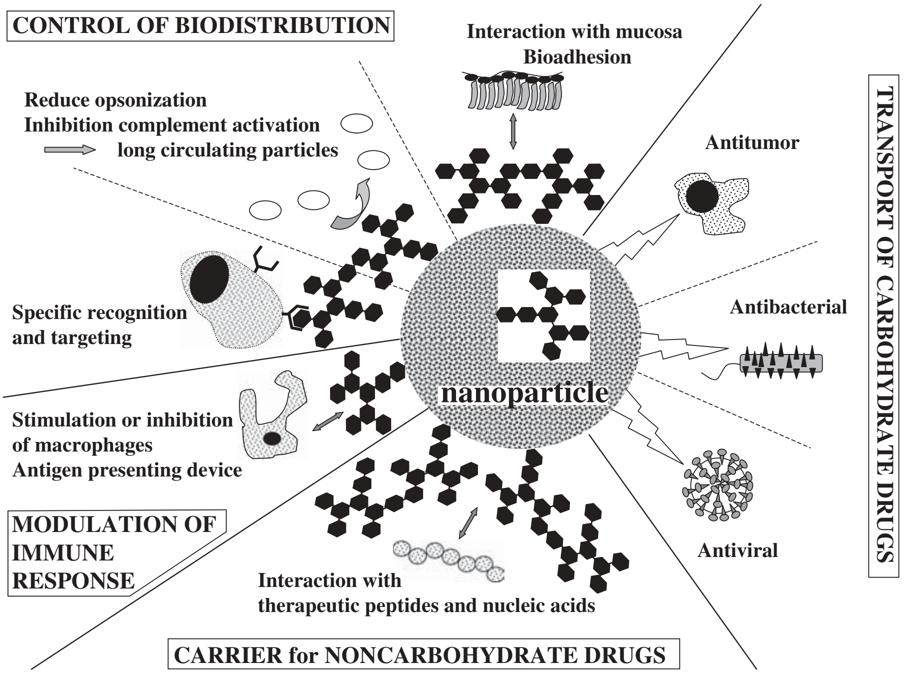

Figure 1.4-1. Diverse carbohydrate properties and their application in the design of a nanoparticle drug delivery system.

delivery systems will be an important point to clarify in the near future for further development for *in vivo* use. Finally, because carbohydrates are implicated in many cell recognition mechanisms and cell signaling phenomena based on high specific interactions with corresponding cell receptors, they may provide very useful tools to increase the targeting specificity of drug delivery systems toward defined cells *in vivo*. Considerable work remains to be done before the potential of carbohydrates will be depicted and will be ready to be integrated into the design of better defined drug delivery systems with more precise functions. This will require the understanding of the role of biological functions of more carbohydrates found in Mother Nature and production or synthesis of sufficient amounts of the defined carbohydrate to clarify their functionalities. From the first results of the experiences done so far on quite simple systems, it may be expected that carbohydrates will allow us to step over a new milestone in the development of drug delivery systems integrating the most recent developments in glycobiology.

1.5.1 INTRODUCTION

There is no good measure of R&D productivity in the pharmaceutical and biotechnology industry because of the long maturation time needed to bring drugs to the market. The R&D investment has a long span of 7–15 years of payback time before drugs are approved. It takes even longer to market in major markets and turn the product into a profitable blockbuster [1–4]. Interim measures of R&D productivity like the number of patents filed and granted, scientific publications (variable impact factor), R&D expenses, and new drug approvals provide only partial measures of success. The real measure of R&D success is the market and profits from blockbuster sales after recovery of development costs. The success of a drug is based on its safety and efficacy established in clinical studies and favorable benefit-to-cost ratio and advantages over current therapy. A marketed product with limited sales and low growth, which barely recovers development costs, is an R&D failure. New projects with potential medicine fail due to lack of safety and/or efficacy. The major objective of the industrial R&D is to plan and execute the shortest development path to gain regulatory approval, strong patent position, and market the drug on a global basis in a short time frame and make it a blockbuster drug by expanding to related indications or new markets [4–8].

Company R&D productivity and efficiency can be measured by its introduction of new billion- and multibillion-dollar medicines through in-house R&D or extramural R&D, licensing, partnership, or marketing rights. Pharmaceutical and biotechnology R&D concentrates essentially on existing therapeutic areas of billion- and multibillion-dollar medicines and/or of first-in-class breakthrough products in new disease areas with double-digit growth. The R&D goal is to create, protect, and extend a company's franchise, to compete with market leaders with products with enhanced safety and efficacy or me-too follow-up for a breakthrough drug. Most current models measure past R&D performance, provide conflicting and variable results, and do not predict current or future outcome.

The modern blockbuster products era started four decades ago with Valium (Roche, diazepam), which was the most prescribed global medicine between 1969 and 1982 with 2.3 billion doses taken in 1978 and the first medicine to achieve peak sales of $200 million. It was later joined by benzodiazapine, antibiotics, and nonstroidal analgesics and by several innovative medicines like Captopril, Capoten, and Mevacor in the 1980–1990 period [9–13]. The period of billion-dollar pharmaceutical brands started 10 years ago and of biotechnology brands about 5 years ago. A commercial report estimated the total blockbuster medicine sales in 2005 at $145 billion and forecasted strong growth in biologics [14].

The profitability of the top pharmaceutical companies and their market value has increased over the years despite a decline in new drug approvals since 1990. Mergers and acquisitions, cost cutting, job elimination, and rationalization of operations achieved short-term profits. The higher R&D budgets failed to increase the number of new regulatory approvals. Moreover, patent expirations on existing blockbuster drugs, frequent and lengthy patent challenges, high prices of medications, drug supplies to poor countries and patients, product injury litigation, drug withdrawals, activists' pressure to shift R&D resources to tropical and neglected diseases, and tough new regulatory requirements for safer drugs and black box warnings hit the industry hard [15–19]. The price multiples or price earnings ratio of innovative pharma was flat or declined over the past 2 years and was converging

with that of generic companies like Forrest and Teva. It is ironic that the industry that took pride in development of new drugs to combat human diseases is now compared with big tobacco and big oil firms [1–4, 15–19].

Profits from billion-dollar (blockbuster) products invariably cover R&D and market failures, fund future R&D investments, pay financial incentives to executives and dividends to shareholders, and fund philanthropy and charity. Fast track regulatory approval, medical need, media coverage, and stories of responding patients contribute to the success of a new medicine. Reports of links to serious adverse reactions, high prices with questionable benefits or low response rates, and black box warnings or regulatory delays have negative effects on the marketing of a new or existing medicine.

The Gold Rush of biotechnology-derived blockbuster bands and the paradigm shift in innovation from pharmaceutical to biotechnology R&D, within biologics towards monoclonal antibodies and from Europe to the United States will be discussed. The successes and failures of biotechnology R&D, criteria for blockbuster brands, global sales of biologics blockbuster brands, changing regulations, cost constraints, public–private partnership to deliver and develop low-cost treatments for tropical diseases, and information resources for biologics will be discussed in this chapter.

1.5.2 REGULATORY APPROVALS

Regulatory approval in the United States, Europe, and Japan is the first step before marketing of a new/future blockbuster; this aspect is first covered before discussions of blockbuster drugs, global sales, and R&D performance.

Regulatory approval of a new medical product is based on the safety and efficacy of a treatment established in open-label and double-blind comparative clinical trials of an adequate number of patients. For life-saving medicines, the number of patients is low, whereas for chronic diseases, the number of patients may go up to 25,000 to define rare and unexpected toxicities or adverse drug reactions. The major markets are in the United States [Food and Drug Administration (FDA)], Europe [European Medicinal Evaluation Agency (EMEA)], and Japan, with common registration requirements for innovative and biotechnology products (International Conference of Harmonization, ICH). Regulatory approval is used to measure the success of a company R&D, but the product may fail to make an impact in the market, only generate modest sale leading to a loss, or barely recover costs of R&D. The R&D success of a company should only be linked to the profitable new blockbuster drugs introduced each year and to a sales increase of $1 billion for existing products.

Biotechnology companies contributed over 60% of the new approvals by the FDA in 2005. Despite the increasing R&D costs [2, 5, 6] and the increasing numbers of active investigational new drugs (INDs) (41% increase from 2001 to 2004), the number of new drug and new molecular entity and first-in-class FDA approvals from top pharmaceutical companies has declined (Table 1.5-1). Since 2001, over 40% of the approved products by top pharmaceutical companies were licensed from smaller biotechnology companies. FDA approvals for new drugs in 2005 included 32 products including Byetta (exenatide, Lilly), Levemir (insulin

TABLE 1.5-1. FDA Drug Approvals 2001–2006

Categories	2006	2005	2004	2003	2002	2001

Active INDs	5445	5029	4827	4544	4158	3883

Data based on information available at www.fda.gov. The European Medicinal Evaluation Agency (EMEA) provides an annual review of drug approvals on its web site, *www.emea.eu.int*.

detemir, Novo Nordisk), Hydrase (hyaluronidase, Prima Pharm), Naglazyme (galsulfase, BioMarin), Copagus (peginterferon alpha-2a+ribavarin, Roche), Revlimid (lenalidomide, Celgene), Nexavar (sorafenib, Bayer, Onyx), and Orencia (abatacept, BMS). The FDA and the EMEA approved breakthrough medicines like Macugen (pegaptanib, Pfizer, OSI) for age-related macular degeneration or Avastin (bevacizumab, Roche, Genentech) and Erbitux (cetuximab, BMS, ImClone) for cancer in 2004 [4]. In 2005, several big pharma companies failed to gain approval for any compounds discovered in their laboratories. Most of the approved drugs were for rare diseases. FDA approved 26 new medicines in 2006 including Januvia (Sitagliptin, Merck) for type 2 diabetes, Sutent (sunitinib, Pfizer), Sprycel (desatinib, BMY), and Zolinga (vorinostat) for cancer. The 8 new biologics approved in 2006 by FDA included Rotateq (rotavirus vaccine, Merck) for gastroenteritis, Gardasil (human papillomas virus vaccine, Merck) for cervical cancer, Zostavax (Zoster vaccine live, Merck) for herpes Zoster in adults, Vectibix (penitumumab, Amgen) for colon cancer, Lucentis (ranibizumab, Genentech, Novartis) for age related wet macular degeneration, inhaled insulin Exubera (Pfizer), Myozyme (alglucosidase alpha, Genzyme) for Pompe disease, and Elaprase (idursulfase, Shire) for Hunter syndrome. The European regulatory agency EMEA approved 51 products in 2006, including first approvals for NCE like Accomplia (rimonabant, Sanofi Aventis) for obesity, Nexavar (sorafenib, Bayer-Schering) for renal cell carcinoma, Thelin (sitaxentan, Encysive) for pulmonary arterial hypertension, Baraclude, Sutent, Sprycel, and Tygacil. Biologics approved included 2 biosimilar human growth hormones, Atryn (r antithrombin alpha, Genzyme) for deep vein thrombosis, Byetta, Elaprase, Lucentis, and Tysabri. EMEA gave first approvals for the new vaccine Daronix (H5N1 whole inactivated antigen, GSK) for avian influenza pandemic and Proquad (measles, mumps, rubella, and varicella, Sanofi Aventis), in additional to Gardasil, Rotateq, and Zostavax. Rotarix (rotavirus vaccine, GSK) was approved in late 2005 and launched in early 2006.

In the past 5 years, at least six or seven products a year, each with peak sales potential of more than $1 billion annually, were terminated in late-stage phase III development or at the new drug application (NDA) filing stage, resulted in market value loss of tens of billion dollars for the affected companies. All big pharma companies like Merck, Lilly, BMS, GSK, and Novartis had their share of phase III failures, regulatory delays, NDA rejections, and requests for additional data [16, 17]. During the past 5 years, 15 drugs with peak sales potentials of a combined $11 billion a year were withdrawn from the market for safety reasons, some of which

had received fast-track priority approval. The resulting product injury litigation cost for just one of the withdrawn drugs, Vioxx, may reach $15 billion (Table 1.5-2) [20, 21]. Black box warnings, media coverage, and links to serious adverse effects resulted in significant sales decline for affected drugs in 2005 (Table 1.5-3). Patient safety and comfort was given priority by the black box warning for increased cardiovascular risks with COX II inhibitors and antidepressants link to suicidal behavior in children. The FDA rightly imposed the requirements for long-term safety

TABLE 1.5-2. Major Drug Withdrawals

Drug	Company	Year	Adverse Effect	Patients Claims	Litigation $
Benoxaprofen	Lilly	1982	Liver failure	2,000	$10 million
Redux/Pondimin (Fen-Phen)	Wyeth	1997	Heart valve problems	130 deaths	16 billion paid
			Pulmonary hypertension	62,000 cases	5 billion reserve
Rezulin (Troglitazone)	Pfizer	2000	Liver failure	400 deaths 4,000 cases	15 billion
Baycol/Lipobay	Bayer	2001	Rhabdomyolysis Kidney failure	100 deaths 1,500 cases	1 billion paid
Vioxx	Merck	2004	Heart attacks Heart failure	10,000 cases	15–25 billion

Two drugs initially withdrawn were allowed back by the FDA in U.S. markets. Lotronex (Alosetron, Glaxo Smith Kline) for irritable bowel syndrome was approved in early 2000 and withdrawn 9 months later due to serious gastrointestinal problems. It was reapproved with restrictions in 2002. Tysabri (Natalizumab, Biogen Idec, Elan) for multiple sclerosis was approved in late 2004 and withdrawn in 2005 due to rare fatal brain lesions and was allowed back in mid-2006.

TABLE 1.5.3 Significant Sales Decline in 2005–2006

Generic Name	Brands	Companies	Indications	Sales $ billion		
				2004	2005	2006
Celecoxib*	Celebrex	Pfizer	Pain	3.3	1.73	2.04
Paroxitine*	Paxil	Glaxo Smith Kline	Depression	3.9	2.2	1.15
Azithromycin**	Zithromax	Pfizer	Antibiotic	1.8	2.02	0.64
Pravastatin**	Pravachol	BMS, Daiichi Sankyo	Cholesterol	5.5	5.0	4.0
Sertraline*	Zoloft	Pfizer	Depression	3.4	3.25	2.11
Simvastatin**	Zocor	Merck	Cholesterol	5.2	4.4	2.8

Sales of top brands in 2005 were down due to safety concern about increased suicidal tendancies in younger children linked to Paxil and Zoloft and increased risk of cardiovascular events (heart attacks) due to COX II inhibitors and withdrawal of Vioxx and added black box warnings imposed by FDA. Medicinal brands with highest sales decrease in 2006 were mainly NCE synthetic products and the loss was due to patent expiry and generic competition.
*Black box warning **Patent Expiry and generics

data for new coxibs and carcinogenicity data before phase III trials for Peroxisome Proliferator activator receptor (PPAR) agonists [20–22].

The current regulatory requirements mandate extensive testing of all biological products even with small differences. Demonstrating that a biosimilar product is as safe and effective as the originator is a difficult task [18, 20]. Europe has taken the lead in biosimilar products by establishing a legal framework for authorization of biogenerics, and EMEA issued several final and draft guidelines in 2006 to cover erythropoietin, insulin, interferon, somatotropin, and granulocyte colony stimulating factor. Sandoz generic human growth hormone was approved in USA and Europe (EU) in early 2006 after a 3-year delay. The recent episode of an unexpected severe inflammation and multiple organ failure adverse reaction in six healthy subjects in phase I trials in England, with an immunomodulatory humanized agonistic anti-CD28 monoclonal antibody for leukemia, multiple sclerosis, and arthritis, and similar reactions in cancer patients in the United States with another anti CD28 antibody, after investigations, may result in new safety regulations for testing biologics and monoclonal antibodies.

The history of modern drug regulations is closely linked to the incidence of drug-induced injury, organ failure, and deaths. Each tragedy linked to marketed drugs resulted in increased regulations and additional testing to prevent future episodes with new drugs of the same class (Table 1.5-4). The Elixir of Sulfanilamide episode resulted in the Food, Drug and Cosmetic Act of 1938 and Thalidomide tragedy in early 1960 resulted in requirements for safety and efficacy testing for drugs in animals and humans.

The withdrawal of benoxaprofen resulted in a 10-fold increase in the number of patients (from 200 to 400 patients/year exposure to 2500 to 5000 patients/year exposure to the study drug) required for newer nonsteroidal anti-inflammatory drugs (NSAIDs) and trials in the elderly, hepatic and renal impairment, and drug interactions. Astra Zeneca total patient exposure in clinical trials submitted for approval of rosuvastatin (12,500) was considerably greater than the 2000–3000 patients submitted for most other marketed statins. Since the withdrawal of troglitazone (Rezulin), no other PPAR agonist has been approved because of the concerns about the class carcinogenicity, hepatotoxicity, and cardiotoxicity [19, 22]. Merck was the dominant R&D-driven and most admired company during the 1980s and 1990s and had one of the highest market valuations in the industry. Thus, a sale loss of $2.5 billion of rofecoxib resulted in a loss of $27 billion market value in one day and another $20 billion within the next month. Analysts have provided estimates of up to $20 billion for rofecoxib litigation. Similarly Pfizer lost $20 billion in one day in market value after discontinuation of its torcetrapib-Lipitor Phase III trials and termination of all trocetrapib (HDL promoter) development projects due to higher number of deaths in the treated group.

The cost of drug development has reached astronomic proportions. Considering the projections of previously contested estimates from 2005 and adding in marketing and manufacturing costs, a new drug for a chronic disease requires $2 billion in investment [2, 23, 24]. Industry critics have doubted earlier estimates, which included interest payments on blocked R&D funds and excluded R&D tax credits. A new GMP facility for a biological product costs an additional $500 million [2, 20]. With the new FDA safety focus, an average drug NDA file for registration for chronic diseases includes data on over 10,000–20,000 patients enrolled in 100–200

TABLE 1.5-4. Regulatory Impact of Health Crisis/Drug Withdrawals

Drug	Year	Regulatory Action
Elixir Sulfanilamide	1937	Food Drug and Cosmetic Act 1938
Thalidomide	1962	Safety and efficacy testing
Contraceptives Risks	1970	Package inserts
Benoxaprofen	1982	Studies in special populations, elderly, renal & hepatic insufficiency, genetic, gender differences
Rare diseases	1983	Orphan drug act
Life-threatening diseases	1987	Treatment IND for life saving drugs
Global regulations	1990	International Conference on Harmonization ICH 1-ICH 7(2006): GMP; GLP, GCP
High costs	1992	Generic drug act (1984 ANDA)
Drug safety	1993	MedWatch
AIDS	1995	Fast-track approval
Fen-Phen	1997	Orlistat NDA 5,000 patients, Safety for new obesity drugs
Rezulin	2000	Carcinogenicity prior to Phase III for PPAR agonists, CV safety for Murgaglitazar in 2005
Tropical/neglected diseases	2000	Public–private partnerships: MMV, GAVI,
Baycol	2001	Safety for new statins, Rosuvastatin NDA 12,500 patients
Vaccines	2002	NDA >20,000–60,000 patients safety, Rotavirus
Vioxx	2004	CV safety in phase III for new COX II inhibitors
		Etoricoxib & Lumiracoxib NDA >25,000 patients
Reduced new drug approvals	2004	Critical Path Initiative: 0 Phase Clinical trials, biomarkers, and clinical trial
Low R&D productivity		design to speed up development
Black box warnings	2005	Reduced sales of affected medicines
Biogeneric guidelines	2006	Europe (EMEA), FDA 2008?

clinical studies over a 7–10-year period. The requirements for life-threatening diseases require only a few thousand patients. The development of a new drug typically takes 7–12 years, and clinical trials for a new vaccine require 25,000–100,000 individuals enrolled in a 2 : 1 ratio in the treatment and placebo groups. The recently approved rotavirus vaccines [Glaxo Smith Kline, Rotarix (in Europe) and Merck, Rotateq (in the USA and Europe)] to protect children from severe gastroenteritis were studied in 60,000–90,000 patients. These two NDAs established a historic record number of patients monitored for safety. With such progression both in the duration of treatment and in the number of patients, new drug development is going to be even more costly (Table 1.5-4).

The FDA's current twin objectives are fast-track approvals of life-saving drugs and long-term safety and efficacy data for chronic conditions. The FDA has taken several initiatives to speed up drug development by introducing 0 phase trials at low doses, improving clinical trials study design and finding validated biomarkers. The objective is to improve R&D productivity [4]. Fast-track approvals contribute greatly to the success of the breakthrough drugs or drugs with significant therapeutic advantage and bring along media interest and coverage of the medical meetings, expert opinion, and raised demand, hope, and awareness of health-care professionals and patients for the new medicine. The FDA and EMEA fast-track approvals have contributed to the blockbuster sales of several new anticancer and antiviral products for AIDS and RSV and new vaccines. The first-year sales for Neulasta, Pegasys, and Avastin were $1300, $760, and $550 million, respectively, due to favorable regulatory and media buzz. Flu Mist (MedImmune) failed to benefit from the U.S. shortage of flu vaccines in 2004, and despite the surge in demand due to Avian Influenza in 2005, because the FDA had limited its use in adults (who do not require flu vaccination) and excluded its use in the elderly and infants.

1.5.3 BLOCKBUSTER HUMAN MEDICINES

The "Gold Rush" of billion- and multibillion-dollar human medicine brands started in 1995 for the pharmaceuticals and in 2000 for the biotechnology-derived brands and will continue to expand in the future. Despite the proclaimed and much heralded "End of the Blockbuster Model" for the pharmaceutical industry, the number of blockbuster drugs, their market share, and contribution to profits for companies has steadily increased (Table 1.5-5).

TABLE 1.5-5 Number of Blockbuster Drugs and Market Share

NCE-New Chemical Entity (Pharmaceuticals); NME-New Molecular Entity (Biologics)
*Global 2006 market estimates by author.

BOX 1.5-1

The success criteria for blockbuster biologics are as follows:

- Life saving, reduction in hospitalization days, critical care, and life support systems
- Improve, maintain, restore, or reverse declining vital/organ functions
- Complete or partial disease remission
- Lifestyle changes, reverse or slow aging process, obesity, diabetes, and hypertension
- High safety and efficacy profile
- Long-term benefits
- Fast-track regulatory approvals
- Strong patent protection and repeated extension for new indications
- Global sales, marketing, and manufacture to meet any surge in demand

From 1991 to 2006, the number of billion-dollar medicines increased 30-fold and their market share by 7-fold and accelerated for biologics brands in 2004 and 2005. The share of biotech sales of the total pharma sales increased in the United States from 4% in 1993 to 15% in 2005. The total number of blockbuster medicinal brands increased to 125 in 2006 and included 35 biologic brands with global sales of biologics reaching $75 billion (Table 1.5-5).

The criteria for blockbuster drugs and diseases with unmet medical need and market success to $5 billion, $10 billion, and $15 billion are as described (Box 1.5-1) [15].

The first effective and safe treatments for Alzheimer's, Parkinson's, chronic graft rejection, permanent graft acceptance, obesity, chronic obstructive pulmonary disease (COPD), adult respiratory distress syndrome (ARDS), sepsis, and vaccines [common cold, respiratory syncytial virus (RSV), severe acute respiratory syndrome (SARS), AIDS, malaria, Avian Influenza, radiation, contraception, emerging new infections] will be multibillion-dollar products [15, 16].

Table 1.5-6 lists the R&D budgets, total sales, % contribution of blockbuster brand sales to human pharmaceutical sales and the list of blockbuster brands by different companies. Only companies with either R&D budgets of over $1 billion or with at least one blockbuster medicine in 2006 are included. The IMS sales figures for the same brand often differed from company figures by more than $500 million for several drugs. The contribution of blockbuster brand sales for top pharmaceutical companies ranged from 37% (Roche) to 74% (Johnson & Johnson). For biotechnology companies, the contribution of a blockbuster brand was even greater and ranged from 66% (Serono) to 98% (Amgen). The contribution of these drugs to the profitability and the market value of the company was even greater. Profits from billion-dollar (blockbuster) products cover R&D and marketing failures in other projects, fund future R&D investments, increase dividend payments to shareholders, fund philanthropy and charity, provide access to medicines for needy patients, and bonuses and motivation to executives. This aspect has not been included in R&D productivity evaluation by commercial reports.

TABLE 1.5-6. Multibillion-Dollar Brand Medicines in 2006

Company	Sales $ Billion (% Blockbuster Sales)		R&D Budget $ Billion		>2 Billion	>$ 1 billion

NA-Not Available

Companies with one blockbuster brand or R&D budget of >$1 billion are listed. Marketing joint ventures like Takeda-Abbott Pharmaceutical, Merck-Schering Plough are not listed.

The % contribution of blockbuster human medicinal brands to the total human pharmaceutical 2005 sales of the company which increased even more in 2006.

Biologics are in **bold**, new blockbuster drugs are in *italics*, brands going off blockbuster status in 2006 are underlined.

In 2006, there was 1 brand with over $12 billion dollar, 3 with over $5 billion, 9 with over $4 billion and additional 8 brands crossed $3 billion annual sales (Table 1.5-7). Although Merck has only four blockbuster drugs, all four had sales over $3 billion each, which is equal to 12 blockbuster drugs. Lipitor alone with sales of over $12 billion is equivalent to 12 billion-dollar drugs. Table 1.5-7 lists all new chemical entities with annual sales over $3 billion in 2006. Lipitor, Plavix, and Advair each had explosive sales growth during the 2002–2005 periods. An increase of over $1 billion a year was recorded with Lipitor during 2000–2005 and for Plavix during the 2001–2005 periods. For Pfizer and Sanofi Aventis, it is like adding a new blockbuster drug each year during the above period.

The U.S. patents on 35 drugs with global sales totaling more than $22 billion expired in the year 2006, resulting in the loss of market to generics. Blockbuster products coming off patent are valued at $27 billion in 2007 and $29 billion in 2008 [17]. Blockbuster brands nearing patent expiration in therapeutic areas like ulcers, hypertension, lipid lowering, depression, schizophrenia, and cancer are replaced by new molecules under patent cover with improved safety and efficacy. Thus, Esmoprazole and two other proton pump inhibitors have replaced Prilosec (omeprazole). Similarly the angiotensin converting enzyme inhibitors class has been taken over by angiotensin receptors blockers with four brands in the multibillion-dollar sales category.

TABLE 1.5-7. Top Brand Medicines with Over $ 3 Billion Sales in 2006

Generic Name	Brands	Companies	Indications	Sales $ billion		
				2004	2005	2006
Atorvastatin	Lipitor	Pfizer	Cholesterol	10.8	12.2	12.9
Fluticasone Salmetrol	Advair	Glaxo Smith Kline	Asthma	4.5	5.5	6.13
Clopidrogel	Plavix	Bristol Myers Squibb, Sanofi Aventis	Atherosclerosis	5.2	6.2	5.55
Esomaprazole	Nexium	AstraZeneca	Ulcers	3.88	4.63	5.2
Amlodipine	Norvasc	Pfizer	Hypertension	4.46	4.76	4.85
Glanzapine	Zyprexa	Lilly	Schizophrenia	4.42	4.2	4.36
Valsartan	Diovan	Novartis	Hypertension	3.1	3.67	4.22
Risperidone	Risperdal	J&J	Schizophrenia	3.0	3.55	4.18
Pravastatin	Pravachol	BMS, Daiichi Sankyo	Cholesterol	5.7	5.0	4.0
Lansoprazole	Prevacid	Takeda, Abbott	Ulcers	3.1	3.8	3.8
Venlafaxine	Effexor	Wyeth	Depression	3.3	3.5	3.7
Montelukast	Singulair	Merck	Asthma	2.6	3.0	3.6
Glatiramer	Copaxone	Teva, Sanofi Aventis	Multiple Sclerosis	1.8	2.4	3.6
Pentoprazole	Protonix	Atlanta, Wyeth	Ulcers	3.3	4.0	3.4
Losartan	Cozaar	Merck	Hypertension	2.8	3.0	3.2
Alendronate	Fosamax	Merck	Osteoporosis	3.1	3.2	3.1

Sales as reported by companies.
Zocor which was 5^{th} in 2005 failed to make the list in 2006.

New-patented products in the same class replaced blockbuster anticancer products in the class taxol, camptothecin, and platinum after patent expiry. In biotechnology-derived biologics, second- and third-generation products with improved properties, like improved insulin, erythropoietin, and peg-interferon, replace the first-generation products. Some companies failed to switch to new patent-covered formulations or analoges like Lilly with Prozac and BMS with Glucophage (no follow-up), and Schering Plough from Claritin to Clarinex. The pharmaceutical industry is very creative in producing me-too blockbuster drugs with extended patent life. There is no reason to believe that this trend will stop in the next 5 years due to looming patent expiration of several blockbuster drugs as some commercial reports have suggested.

1.5.4 BIOLOGICS GOLD RUSH

IMS [12] data estimated the global pharmaceutical market at $600 billion and biotechnology products at $52 billion in 2005. Ernst and Young [1] estimated the total biotechnology product sales at $54.6 billion in 2004 and $63 billion in 2005. Datamonitor estimated the 2005 global biotechnology market at only $40 billion. All sales forecasts are on the low side as the total sales of the listed biotechnology products in Tables 1.5-8 and 1.5-9 alone were $60.4 billion in 2005 and $71.25 billion in 2006. There are 300 approved biotech products in the United States and Europe, 100 under regulatory review, and another 400 in advanced clinical trials for 200 diseases [1].

Several brands of EPO, TNF inhibitors, interferon, insulin, and GCSF had sales of over $1, $2, and $3 billion each in 2004 and 2005. The period 2002 to 2005 recorded a sales increase of over $1 billion per year for TNF inhibitors. The top five best-selling human medications were all biotechnology drugs by sales in 2005, apart from Lipitor. There were five biologic brands with over $3 billion and six brands with over $2 billion in sales in 2005. As several companies market erythropoietins, interferons, insulins, GCSF, and human growth hormone under different brand names, these proteins rarely make bestsellers lists in commercial databases, unless taken together (Tables 1.5-8, 1.5-9) [22, 25].

A review of several therapeutic areas and brands indicates intense market competition for market leadership and change of market leadership among different brands and fast growth areas (Tables 1.5-8, 1.5-9). This has been previously observed with me-too or follow-on pharmaceuticals. Losec overtook Zantac, which had overtaken the first-in-class Tagamet; Enalapril over Captotril (Capoten); and Lipitor over Zocor and the first-in-class Mevacor. Lipitor has retained market dominance despite the arrival of superstatin Crestor and newer combination products. Diovan overtook the first-in-class Cozaar in 2004, for the market leadership of the angiotensin II receptor blocker ARB antihypertensive agents [22]. Astra Zeneca retained its dominance of the antiulcer market by successful switching patients to Nexium and limiting the decline in Losec sales after patent expiration. The success of Atlanta to launch a blockbuster antiulcer Protonix shows that follow-on patented me-too drugs carry low risk and high rewards (Table 1.5-7). Monoclonal antibodies for cancer and immunoinflammatory conditions had global sales of $20.5 billion in 2006 with tumor necrosis factor blockers accounting for

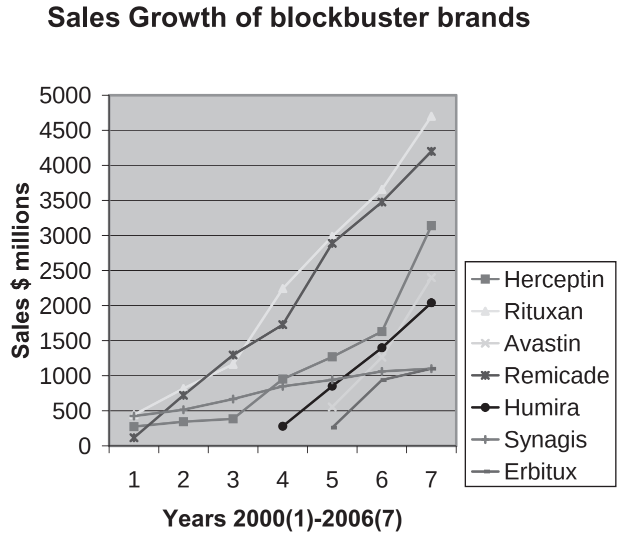

Figure 1.5-1. Blockbuster monoclonal antibodies sales growth.

$10.6 billion. Vaccines were second with global sales reaching $15 billion. The other major categories of biologic brands with global sales were erythropoietins for anemia with $12 billion, traditional and newer insulins like long acting at $9 billion and interferon for hepatitis and multiple scelrosis at $7 billion.

Erythropoietin has remained the best-selling human medicine for the past 3 years, followed by Lipitor (Atorvastatin), and both of these had over $12 billion in sales [20–22]. The sales of erythropoietin in Japan were over $1 billion. Tumor necrosis factor inhibitors, interferons, and insulins with, respectively, sales of $8.6 billion, $7.3 billion, and $6.5 billion in 2005 were the third, fourth, and fifth best-selling products after EPO and Lipitor (Table 1.5-8) [20–22, 24, 25]. The time taken to reach $1 billion annual sales for monoclonal antibodies has varied and was much faster for follow up and cancer products (Fig. 1.5-1). Rituxan is the leading antibody since 2003 by sales. The growth of Avastin and Erbitux has been much faster as compared to Herceptin and took only two years to reach $1 billion sales.

1.5.5 R&D OVERVIEW

An overview of the blockbuster medications during the past few years and a comparison of R&D productivity clearly show an ongoing paradigm shift of innovation from Europe to the United States and from pharmaceutical to biotechnology R&D. A comparative analysis of R&D productivity of pharmaceutical and biotechnology firms is provided.

Pharmaprojects lists over 7300 drugs in active R&D, whereas the PHRMA site using Kluwer Health Adis R&D Insight lists over 10,000 active R&D projects. The

number of new drugs in R&D has almost doubled to 1970 drugs in 2004 from 1010 drugs in 1995 [1]. There are over 300 approved biotech products in Europe and the United States, 100 under regulatory review, 200 in late phase II–III clinical trials, and 800 in early clinical trials [1, 16, 20]. Monoclonal antibodies outnumber all other biologics combined in all stages of preclinical and clinical development. The biotechnology industry spent over $23 billion on R&D and generated over 7000 patents in the year 2005, with patents in cancer leading over other therapeutic categories. The highest number of patents was issued for cancer, and the success of cancer vaccines is attracting a lot of R&D funds. Only a strong R&D pipeline contributes to long-term growth of the company.

Several pharmaceutical companies spent over $3 billion on R&D in 2005 for a portfolio of 80–150 projects, of which 50–80 were in clinical development. In general, only about 30% NCE are truly innovative, the rest are me-too products or line extensions. About 30–40% of the projects of big pharma are licensed in from other sources [2, 3]. The share of the top 10 global R&D companies in the innovative first-in-class type of new molecular entities has steadily decreased over the past decade. It now takes 10–15 years to bring a product from discovery to markets. The success rate has decreased over the years, and out of a million compounds screened in highly automated computerized systems High Throughput Screening (HTS), only 250 advanced to become development candidates for additional testing [16].

All major pharmaceutical companies run their own discovery, development, licensing, partnership, manufacturing, marketing, and sales for the majority of their product pipelines and portfolios with a relatively high risk and investment [1, 3]. Strategic review, analysis, and consulting firms have prompted big pharmaceutical firms to shift focus to targeting specific populations or disease areas like the biotechnology companies and shift R&D resources to vaccines, biologics, and monoclonal antibodies that have higher rates of success, form partnerships in all stages of drug discovery and development to reduce risks and share rewards and focus on disease and needs of the patients, and operate as strategic business units [5, 9].

There has been a paradigm shift in innovation from the pharmaceutical to biotechnology R&D based on the number of new billion-dollar biologics introduced. There is a clear indication from Table 1.5-6 that biotechnology companies with smaller R&D budgets were more efficient in creating new blockbuster brands. [10, 11, 14, 16]. With the large-scale production of antibiotics, vaccines, and insulin during the post-World War II period, the pharmaceutical industry acquired and developed skills to manufacture, market, and supply medicines worldwide and retains its edge over biotechnology companies. An earlier paradigm shift from academic to industrial R&D happened in the 1970–1980 period. Pharmaceutical firms' R&D laboratory scientists won Nobel prizes and made important discoveries leading to new drug classes like ACE inhibitors, proton pump inhibitors, NSAIDs, and immunosuppressive agents for organ transplantation. The recent paradigm shift during the past 5 years has been the transfer of innovative R&D from Europe to the United States in parallel with the shift from pharmaceutical to the biotechnology R&D [25–28]. The strength of the biotechnology industry, university industry relationship, groundbreaking discoveries, National Institutes of Health (NIH), absence of price controls, and rapid uptake of high-price new treatments to avoid

potential litigation from patients have attracted R&D investment from European and Japanese companies.

1.5.5.1 R&D Productivity

There was no clear-cut relationship between a higher R&D budget and creation of new blockbuster medicines. If one only goes by the number of blockbuster medicines, the top four companies did not increase the number of such drugs in the year 2005 from 2004. Several companies like Pfizer, Merck, BMS, and Wyeth had decreased numbers, whereas Sanofi Aventis, Astra, Roche, and Amgen had increased numbers. The international R&D expansion activities, research capabilities, and patent output of 65 Japanese pharmaceutical firms from 1980 to 1991 were studied. It was observed that firms benefited from international R&D only when they had in-house existing research capabilities in the underlying technologies [29]. Another study of the Japanese pharmaceutical industry innovative capabilities from 1975 to 1995 found that the unattractive home market pushed these firms into trivial innovations [30]. The global expansion of the Japanese companies and their creation of blockbuster drugs do not support the above conclusion. German majors like Bayer, Schering, and mostly generic Merck failed to create any new blockbuster medicine during the past few years, indicating the decline of the German industry from global to regional levels. Boehringer Ingelheim and mid-sized Atlanta were able to add new billion dollar molecules. The German industry moved strongly in 2006 towards consolidation and mergers. Bayer purchased Schering and Merck made a move into biotechnology by acquiring Swiss Serono. Atlanta was overtaken by Danish Nycomed and another mid-size, Schwartz, was absorbed by Belgian UCB. These moves reflect a desire to consolidate marketing and R&D.

Drews [31, 32] raised concerns about the low R&D productivity gap despite the mergers in the early and late 1990s. These mergers in fact resulted in reduced R&D productivity to produce new approvals and blockbusters. Glaxo Smith Kline of today was formed from Glaxo, Wellcome, Smith Kline French, Beecham, Beckman, Affymatrix, Sterling, and a host of other smaller companies. Similarly Sanofi-Aventis was a merger of the following component companies: Hoechst, Rhone Poulenc, Marion Merell Dow, Roussel, Rorer, Sanofi, Connaught Labs, Merieux, and Synthelabo. Pfizer acquired Pharmacia, Werner Lambert, Parke Davis, Searle, Upjohn, and a host of other smaller companies. This applies to most top pharmaceutical companies except Merck. Mergers have started within the biotechnology industry, like Amgen taking over Immunex and Tularik, and Biogen-Idec and pharma companies like Roche taking over Genentech, Novartis-Chiron, and J&J—Alza, Centocor. Astellas was formed from the merger of Fujisawa and Yamanouchi, and Daichi and Sankyo merged in 2005.

As several competitive pharma R&D units were merged, several projects were terminated or given low priority and funds, and R&D staff was reduced or shifted, resulting in high turnover and low morale. The bigger company centralized R&D units became more risk averse. Several once promising areas of research like combinatorial chemistry produced huge chemical libraries with minor structural variations; HTS, gene therapy, proteomics, antisense, vaccines for AIDS, sepsis, RSV, and malaria, Alzheimer's disease, and Parkinson's disease have increased our

knowledge and understanding and the number of targets. However, no breakthrough blockbuster medicine has emerged out of these new high-speed and costly technologies. Demain [33] attributes such failure to the elimination of natural products and extracts from the HTS screening and recommends including natural products in HTS screens. The partnerships between different companies for R&D and marketing alliances/joint ventures to develop products have a higher probability of blockbuster success [17, 34]. Historically, blockbuster drugs were aimed at the larger markets of depression and ulcers. Other large-market indications like cholesterol and lipid lowering agents, antihypertensives, osteoporosis, asthma, and schizophrenia emerged due to the availability of effective and safe drugs (Table 1.5-7). These therapeutic areas have dominated the pharmaceutical markets for the past two decades. Several of these drugs were discovered and initially developed by smaller companies and licensed to big pharma for marketing and late development.

The successful biological products were developed to treat anemia, cancers, infections, and inflammatory joint diseases. The biologic blockbuster medicines have significantly contributed to the recent increase in the number of such drugs and made several previously ignored indications like multiple sclerosis, pulmonary arterial hypertension, anemia, cystic fibrosis, vaccines, and age-related macular degeneration commercially attractive and highly competitive areas for new drug development (Tables 1.5-6, 1.5-7) [1–4, 16, 20, 34–37]. The demand for new and better medications remains strong as currently only about one third of the over 35,000 human diseases have some treatment options available.

Based on new product approvals and creation of blockbuster brands, the success rates of biotech products are higher as compared with traditional chemically derived small-molecule new chemical entities. The biotechnology industry growth and market valuation has outpaced the pharmaceutical industry during the past 2 years. The increasing dependence of big pharma on small biotech is evident by the increasing number of licensing and R&D funding deals. The bulk of new medications approved in the years 2003–2005 originated in small biotech companies [35–39].

The higher R&D productivity of biotech companies is linked to their close relationship with academic biomedical research, higher risk taking by boldly testing first-in-class, and new concepts and designs in clinical trials, which are driven by unmet medical needs even for diseases for which the pharmaceutical industry has shown no interest. The R&D failure rate of biotech companies is much higher as compared with big pharma testing of follow-on or me-too drugs [1–3, 16, 20, 32–35]. For blockbuster drugs, the biotechnology companies have followed the standard pharmaceutical company strategy. They have followed fast-track approval for the first indication in an orphan or niche disease with high unmet medical need, market the drug at high prices, and expand approvals in other related diseases and new markets.

The risk associated with the development of human antibodies and biologics is lower than that with an NCE with a probability of success at 8% in phase I. Chimeric or humanized antibodies have a much higher success rate at the phase I stage (25%), due to recent advances in target selection and recombinant technology. New developments include techniques for converting murine monoclonal antibodies to mouse–human chimeric antibodies, for humanizing the antibodies, and producing

human antibodies using transgenic mice. These approaches minimize or eliminate the immune responses and rejection associated with the earlier murine antibodies [37–40]. The strong sales and demand from cancer and arthritis patients have outdated almost all commercial market research reports and sales forecasts for monoclonal antibodies. The higher success rate, low cost of entry and IND filing, and use of human/humanized monoclonal antibodies—with 6 blockbuster brands, half of which arrived in 2005, and the potential for more billion-dollar monoclonal antibodies to reach the market—has fueled the current Monoclonal Antibody Gold Rush. The bandwagon has been joined by 200 companies with hundreds of new projects and targets and has attracted billions of dollars in R&D investment. Factors contributing to the success are unmet medical needs of patients, lower cost of entry into R&D and production, the overcoming of technical hurdles in large scale manufacturing, and availability of humanized or fully human monoclonal antibodies.

The R&D productivity of the big pharma with biotech companies has been compared for the period 1998–2004 in commercial reports [1–3]. The R&D expenses and the FDA approvals of the new molecular entities were linked [16, 20, 23, 24]. The biotech approvals were less than 10, and the pharma NCE approvals declined from 25 to 15 from 1998 to 2005. The decline of the first-in-class medications from big pharma was even more dramatic. The biotech approvals were more numerous than pharma approvals in 2003 and 2004, and the trend reversed in 2005. The big pharma R&D expenses were $50 billion in 2004, resulting in 10 NME approvals, whereas biotech approvals were 20 for an R&D budget of $20 billion. Tables 1.5-6 and 1.5-7 list the top-selling major therapeutic proteins and biological brands created by the biotechnology industry since 1997. The list provides therapeutic areas of blockbuster brands, marketing wars between different brands for market leadership, and shift to newer brands with improved properties.

1.5.6 R&D SUCCESS

The biotechnology industry had its share of major R&D and clinical trial success. The big gains for biotech products are mainly in anemia; cancer; TNF alpha inhibitors; human insulin with short, mixed, and long duration of action; interferon for multiple sclerosis and hepatitis C; monoclonal antibodies for cancer; RSV; and immuno-inflammatory diseases. This success has resulted in attracting top pharmaceutical companies and R&D funds for biosimilar products with improved properties. It is easier for start-up companies in the above areas to attract capital and angel investors or to conclude licensing deals and find marketing partners.

As EPO, insulin, interferon, and monoclonal antibodies are covered in other chapters, only a brief resume will follow of these major success stories of biotechnology R&D.

1.5.6.1 Erythropoietin

Erythropoietin, Lipitor, and TNF inhibitors are likely to cross the $15 billion mark within the next few years. Amgen commercial success with its EPO brands has attracted several competitors with which Amgen has been involved in costly and protracted patent and marketing litigation to protect its franchise. Erythropoietin

is the top litigated biotech product. In 2005, over 20 erythropoietins were in development either as follow-on or improved biosimilar products [20, 41]. Numerous players are striving to dominate this market, including, among others, Amgen, J&J, Roche, Chugai, Shire, Kirin and Elanex, Teva, Sandoz, Stada, Cangene, Microbix and Gene Medix. Amgen patents expired in Europe in 2004 but are valid in the United States until 2015, and it has shifted patients to its new Aranesp brand. In Europe, two forms of rEPO are available: Eprex (J&J) and NeoRecormon (Roche). Two other forms Dynepo (Shire, Sanofi Aventis) and CERA (Roche, PEG-EPO) are likely to be approved in 2007. Amgen has filed a preemptive patent infringement against Roche for its PEG-EPO (CERA), thereby delaying its market launch in the United States. The FDA's recent alert about erythropoietin (EPO) use in cancer patients with over 12 gm/dL of hemoglobin and the black box warning linking EPO agents to increased mortality, cardiovascular events, tumor growth, and hyptertension are likely to result in market and sales decline in 2007. The FDA advised doctors to use the lowest dose of EPO for patients to achieve hemoglobin levels of 12 gm/dL.

1.5.6.2 Tumor Necrosis Factor Inhibitors

The commercial success of antitumor necrosis factor monoclonal antibodies like Remicade (Infliximab), Humira (Adalimumab), and Enbrel (Etanercept) in rheumatoid arthritis is due to better tolerance and superior efficacy as compared with older disease modifying antirheumatic drugs (DMARDs) with variable and short response rates but higher toxicity leading to either their low clinical use or market withdrawal (Table 1.5-6) [42–44]. TNF inhibitors with methotrexate provide a response rate of 50–60% by the FDA, American and European Rheumatology remission criteria. Risks associated with TNF-blockers are serious infections, congestive heart failure, demyelinating diseases, and systemic lupus erythematosus, but in most cases, they can be identified and managed. Biological agents have revolutionized the treatment of autoimmune/inflammatory diseases like rheumatoid arthritis and Crohn's Disease (CD). Enbrel was the first TNF inhibitors approved for treatment of rheumatoid arthritis patients in 1998. The FDA (fast track) initially approved Remicade for Crohn's Disease the same year. Both agents were tried and failed to show any efficacy in early trials in cancer, sepsis, and congestive heart failure. Both Enbrel and Remicade are approved for rheumatoid arthritis (RA), psoriatic arthritis (PsA), and ankylosing spondylitis (AS). There is some differentiation as Enbrel is effective in juvenile rheumatoid arthritis (JRA) and psoriasis (Ps). Remicade is approved for CD and ulcerative colitis (UC) and has shown efficacy in sarcoidosis and Wagener's granulomatosis. The third agent, Humira, is approved for use in RA, PsA, AS and CD.

After the launch of Enbrel, the demand for patients during the first 3 years of marketing was so strong that Immunex and its marketing partner Wyeth (American Home Product) were unable to increase good manufacturing practice (GMP) production to meet the surge in demand. There was a 30% shortfall, and these patients drifted to Remicade. Only Amgen's takeover of Immunex in 2002 resolved the supply problems to meet demand. Remicade, with its approval in UC and CD, was the market leader and overtook Enbrel in sales in the 2002–2003 period. Enbrel

has been the current market leader in its class since 2004. Kineret (anakinra, Amgen) is a recombinant, nonglycosylated synthetic form of the human interleukin-1 receptor antagonist (IL-1Ra) that mimics the body's endogenous mechanism for regulating IL-1 and is approved for treatment of RA patients not responding to DMARDs and TNF inhibitors. Kineret (anakinra, Amgen) has failed to gain a significant market share of the RA patients because it cannot be used in combination with TNF inhibitors. Orencia (Bristol-Myers Squibb abatacept) is the first T-cell costimulation modulator approved for the treatment of RA and was marketed in early 2006. Orencia in combination with TNF inhibitors or other biological agents like Anakirna is not allowed. Roche Rituxan, a monoclonal B-cell-specific antibody to CD20 (MabThera), was approved for use in RA patients along with methotrexate.

Recent R&D failures include Biogen Idec, Lilly-ICOS, and Alexion products in clinical trials. The Roche monoclonal antibody to the IL-6 receptor for RA (MRA) has shown efficacy in RA patients not responding to methotrexate and TNF inhibitors. If long-term safety, efficacy, and remission of new biologics are established in osteoarthritis trials, it will be an important therapeutic advance and create a large market.

1.5.6.3 Psoriasis

Alefacept (Amevive, Biogen Idec) and Efalizumab (Reptiva, Xoma, Genentech, Serono), the two monoclonal antibodies, which block the activation of T cells, were hailed as major advances in the treatment of psoriasis. The sales of Reptiva were \$112 million and \$160 million and of Amevive were \$48 and \$15 million in 2005 and 2006 below initial sales forecasts mainly due to competition from TNF inhibitors [45]. The technical success of R&D of non TNF biologicals for treatment of psoriasis has not translated into commercial success due to the large clinical data base and dominance of TNF antagonist products.

1.5.6.4 Insulin

A review of the insulin blockbuster brands in Table 1.5-10 indicated the market entry of a new company Sanofi Aventis to challenge the market dominance by Lilly and Novo Nordisk and the rapid growth of the newer insulin analogs with improved properties. The aim of the R&D is to move away from several daily insulin injections. There has been intense R&D activity during the past few years to provide patients with improved insulin that is fast acting, of a long duration, and dual action. This approval and launch of the first inhaled insulin Exubera (Pfizer) should expand the market, and initial peak sales projections are \$3 billion per year depending on its long-term effects on lung functions. The UK cost effectiveness agency has determined that the high costs of Exubera are not justified as it does not offer any advantages over insulin injections, and concerns about long term toxicity to lung cells has delayed marketing by Pfizer in USA despite FDA approval. Table 1.5-8 lists new improved marketed and approved insulin analogs and those in development [46–48].

TABLE 1.5-10. Improved Insulin Analogs

Company	Product	Description	2006 Sales Status $ Million
Sanofi Aventis	Lantus Apidra	Insulin glargine Insulin glulisine	2200
Novo Nordisk	Insulin Aspart Levemir	Rapid insulin Insulin detemir	1700
Lilly/Amylin	Byetta	Exenatide incretin mimetics	430
Pfizer	Exubera	Inhaled insulin powder	Approved
Lilly/Alkermes	AIR Insulin	Insulin powder	Phase III
Mannkind	Technosphere Insulin	Powder liquifies in lungs	Phase III
Novo Nordisk Aradigm	NN 1998	Aerosol Mist	Phase III
Kos	KI 02 212	Liquid suspension	Phase II
Novo Nordisk	NN 344 NN 5401	Long-acting insulin, improved analog	Phase I

1.5.6.5 Interferon

Interferon alpha in combination with ribavarin for the treatment of hepatitis C is a commercial success. The biotech industry had its once promising drugs failing in clinical trials, and drug withdrawal by Biogen and Elan of Tysbari (natalizumab) for multiple sclerosis due to deaths of some patients from a rare brain infection was a setback. Multiple sclerosis (MS) is a neurological disorder affecting 2 million patients worldwide. Teva/Sanofi-Aventis Copaxone joined the three interferon blockbuster brands for the multiple sclerosis market led by Avonex in 2005. The total MS market sales reached $7 billion in 2006. Copaxone and return to market of Tysbari will expand the market and replace older interferon brands. Interferon sales slowed in 2005 after 2 years of rapid growth due to the new use of a poly ethylene glycol (PEG)–interferon combination with ribavarin in hepatitis C and withdrawal of Tysabri.

Biologics are important for new emerging threats, bioterrorism, and infectious diseases such as pandemic influenza, West Nile Virus (WNV), SARS, antibiotic-resistant tuberculosis, and the prion agent that causes the human form of mad cow disease, variant CJD. New vaccines to protect against HIV, RSV, anthrax, small-pox, hepatitis, malaria, WNV, and bird (avian) flu are in clinical testing [49–51]. Monoclonal antibodies and peptides have made a great contribution to the treatment of cancer patients, and several antibodies and peptides have become blockbuster drugs. Many of these antibodies carry black box warnings. Several new anticancer agent brands are blockbuster drugs, and the list grows each year [52–54].

The advent of Macugen and Lucentis to treat age-related macular degeneration and endothelin antagonists (Tracleer, Thelin, Ambrisentan) and prostacyclin analogs (Epoprostenol, Treprostinil, Beraprost, Iloprost) to treat pulmonary arte-

rial hypertension are important treatment advances. Both of these therapeutic areas have several active R&D projects at the approval and the clinical trial stage.

Roche has been the most efficient and productive industrial R&D during the past 2 years. The association of Roche with 5 of the top 10 biotech products is a tribute to its success in acquiring Genentech, an investment in biotechnology and its alliance with biotech companies. Amgen and Genentech market cap was in the $90–$100 billion range in early 2006 but has come down recently, and was still higher than Wyeth, BMS, or Schering Plough. Other big companies like J&J and Lilly have a strong pipeline of biological products in development.

1.5.7 R&D FAILURES

The biotechnology industry had its share of major R&D and clinical trial failures. The big late-stage setbacks for biotech products are mainly in Alzheimer's disease, sepsis, and vaccines for RSV, malaria, and AIDS. Despite such failures, the R&D funding by big pharma continues in Alzheimer's and sepsis but has bailed out in vaccines and infectious diseases. The long history of failures has made it difficult for a biotechnology company working in the above areas to attract venture capital and angel investors or to conclude licensing deals or find marketing partners.

1.5.7.1 Alzheimer's disease

Alzheimer's disease (AD), the most common cause of cognitive impairment in older patients, is characterized by the development of senile plaques and neurofibrillary tangles, which are associated with neuronal loss affecting to a greater extent cholinergic neurons. A cascade of pathophysiological events is triggered in AD that ultimately involves common cellular signaling pathways and leads to cellular and neural networks disfunction, failure of neurotransmission, cell death, and a common clinical outcome. The viable neurons remain an important target for therapeutic intervention at each stage of disease evolution. Currently, symptomatic drugs inhibiting the degradation of acetylcholine within synapses and more recently glutamate receptor antagonists represent the mainstay of therapy. However, interventions able to halt or slow disease progression (i.e., disease-modifying agents) are necessary. Although much progress has been made in this area, there are currently no clinically approved interventions for AD classed as disease-modifying or neuroprotective drugs [55].

The first four approved and marketed drugs Aricept (Pfizer, Eisai, donepezil), Reminyl (J&J, galantamine), Exelon (Novartis, Rivastigmine), and Cognex (Pfizer, Tacrine) are reversible cholinesterase inhibitors [55]. Memantine is an *N*-methyl-D-aspartate (NMDA)-type glutamate receptors antagonist, which is the first in a new class of AD medications. Glutamate is the most common excitatory neurotransmitter in the central nervous system, and the modulation of glutamatergic neurotransmission is a major target for the treatment of Alzheimer's disease. Memantine was developed by Merz and licensed to Forest for the U.S. and Lundbeck for the European and international markets. Memantine is marketed under the brands Axura and Akatinol by Merz, Namenda by Forest, and Ebixa by Lundbeck. Clinical studies of the safety and efficacy of memantine for other neurological disorders, including glaucoma and other forms of dementia, are currently

ongoing [56]. A series of second-generation memantine derivatives are currently in development and may have better neuroprotective properties than memantine. Recent failures have included Axonyx, Forest Labs, Elan, Myriad, and Neurocrine. Elan and Wyeth (American Home Products) ended trials of their Alzheimer's vaccine (AN-1792) in 2002, after patients suffered swelling of the central nervous system or inflammation of the brain and spinal cord. The vaccine activated the patient's own immune system to attack a protein called beta-amyloid that is implicated in Alzheimer's. Several tested drugs provided good results in phase II but failed in phase III. Some drugs showed a biphasic response curve. Several muscarinic receptors agonists failed in phase II–III trials.

1.5.7.2 Anti-infective Exodus and U-turn

During the 2001–2003 period, several companies, namely Aventis, Bristol Myers Squibb, Eli Lilly, Roche, GlaxoSmithKline, Proctor & Gamble, and Wyeth, eliminated or greatly curtailed their anti-infective R&D [57]. The reasons for pharmaceutical companies leaving the anti-infective area were slow growth in the West, unpredictable and seasonal demand, pricing pressure to donate supply or at cost to poor countries and patients, the vaccine unprofitability, and low investment in vaccine companies. Vaccine companies were scared and hesitated to launch new vaccines with sales in the tens to hundreds of millions of dollars because of the threat of billion-dollar punitive damage settlements. The liability issues and current regulatory requirements for new vaccines have a negative impact on vaccine R&D. Public–private partnerships, along with NGO and public initiatives, have resulted in increased funding of newer vaccines for tropical, orphan, and neglected diseases like malaria, tuberculosis, and leishmaniasis.

Vaccines were back in favor and were highlighted in R&D portfolios of major companies (Sanofi Aventis, Glaxo Smith Kline, Merck, Novartis, and Wyeth). Global sales in 2006 were $15 billion because of scare about avian influenza, bioterror organisms, and new emerging infections like SARS. Introduction of new cancer and rotavirus vaccines will greatly expand the vaccine market in the next 2 years. During the past few years, the spotlight on SARS, Avian Influenza, new emerging infections, and bioterror agents have seen a few big companies like GSK, Merck, Novartis, and Sanofi Aventis declaring vaccine production as a high priority area of R&D. It is ironic that Roche, which had closed its anti-infectives R&D unit, was in the news to supply its antiviral Tamiflu to stop Avian Influenza. The success of Prevenar (Wyeth), the explosive demand for influenza vaccines, and the approval of two new Rotavirus vaccines with huge safety databases have brought back the interest of the industry in vaccines. Pediatric vaccines, influenza, and hepatitis B vaccines have been the leading categories. Although the demand for influenza vaccine was strong, MedImmune FluMist 2005 sales of $21 million remained below forecast, due to high cost and its use limited to younger patients (5 to 17 years of age, and healthy adults, 18 to 49 years of age). A new refrigerator-stable formulation was 55% more effective in children in the age range of 6 and 59 months. New vaccines for cancer, RSV, AIDS, and malaria will expand the market [57–61]. Vaccines have been the most cost-effective treatment and probably were undervalued, but the higher prices of newer vaccines in the $100–$400 range are likely to keep even these out of the reach of poor patients [49–51].

1.5.7.3 RSV

The commercial success of a new product in most indications or additional use in new indications results in much higher R&D activity and funding by competitors. However, the success of Synagis (Palivizumab) in RSV and Drotrecogin alpha (activated protein C) in sepsis has resulted in industry bail-out due to the failure of several promising projects during the past decades [57, 62, 63]. The new drugs in development and currently approved drugs for RSV were reviewed recently and are listed in an updated Table 1.5-11 [57], which confirms a significant decline from over 25 to only 4 active RSV projects. Several RSV vaccines and antivirals, which were in phase III testing during the last review, are considered terminated either due to low efficacy or safety concerns due to adverse effects. These projects are not listed in the companies' current R&D pipeline, but many commercial databases still list these as active projects.

1.5.7.4 Sepsis

Severe sepsis or septic shock occurs when an infection (bacterial, viral, fungal, or parasitic)—often the result of trauma, surgery, burns, or cancer—triggers a cascade of immune system responses that can lead to acute organ disfunction and often death [62]. The death rate from severe sepsis ranges from 30% to 50%. Every day 1400 people worldwide die from severe sepsis. The International Sepsis Forum estimates that more than 750,000 individuals develop severe sepsis in North America each year, with similar estimates for Europe, and all need to be actively treated in the hospital. Sepsis kills 215,000 people annually in the United States and is the most common cause of death in noncoronary intensive care units. The annual costs associated with the treatment of patients with severe sepsis are estimated to be US$17 billion. The incidence of sepsis is expected to increase to 2.2 million per annum in the leading markets over the next 10 years as the elderly population grows. Thus, a safe and effective treatment, which saves lives, can be a blockbuster drug [62, 63].

Activated protein C (Drotrecogin alpha, Xigris) is the first and only drug shown to cure those suffering from sepsis. It had sales of $214 million and $192 million

TABLE 1.5-11. Marketed and R&D Development Products for Prevention of RSV

Product	Characteristics	Company	Sales 2006 Status
Palivizumab Synagis	hAnti F-glycoprotein	MedImmune	$1100 million
RespiGam	Immunoglobulin	MedImmune	negligible
Ribavarin	Antiviral	Valeant	Generics
Motavizumab Numax	Monoclonal antibody	Medimmune	Phase III
A 60444	Antiviral	Arrow	II
Live attenuated	RB/HPIV3-RSV-A/B	MedImmune	I
ALN RSV01	RNAi	Alnylam	I

Notes: Several commercial databases still list RSV vaccines and antiviral in clinical development by companies, e.g., Wyeth, Sanofi Aventis, and Glaxo Smith Kline. These projects are considered discontinued as companies' websites do not list any active RSV projects or there has been no new information for the past 3 years after completion of phase II or III trials.

in 2005 and 2006, respectively. In Lilly's PROWESS clinical trial, drotrecogin alpha only reduced the absolute risk of death by 6%. It seems that, with a $6800 price tag, this was insufficient to persuade physicians to prescribe the drug outside the most severe cases. In 3.5% of drotrecogin alpha-treated patients (compared with 2% of placebo treated patients), the drug also increased the risk of serious bleeding events. Another obstacle to drotrecogin alpha's widespread adoption is that it can be hard to identify candidates for treatment [62–64].

Drug development for sepsis and septic shock has been disappointing: Numerous agents have demonstrated promising activity in early clinical phase I/II and then failed to show significant efficacy in phase III trials. In recent years, several biotechnology firms have gone bankrupt or were taken over trying to develop a drug to combat sepsis. Billions of dollars have been wiped out in market values of the biotechnology companies due to failures of their drugs in sepsis.

In the early 1990s, two promising drugs named Centotoxin and E5 from Centocor and Xoma were in a race to be the first effective treatment. The two drugs had shown efficacy in early phase II clinical studies and were rushed into large-scale phase III clinical studies. Both drugs failed to show improvements in mortality in phase III and were rejected by the FDA and its advisory committee in 1992 [62].

Randomized trials of anti-inflammatory therapies agents, including NSAIDs and corticosteroids, failed to show improvement in survival from sepsis and septic shock. Three monoclonal antibodies to endotoxin were tested in clinical trials, and all failed to improve survival from sepsis and septic shock. The Centocor project went down in 1992, and drugs from Chiron, Xoma, and Synergen failed in 1994. Many anticytokine therapies have not improved survival from septic shock. These trials include the use of naturally occurring antagonists to tumor necrosis factor and interleukin-1, antibodies to tumor necrosis factor, bradykinin antagonists, ibuprofen, and a platelet-activating-factor antagonist. Additional endotoxin-directed therapies being studied were the use of bactericidal permeability-increasing factor, soluble CD14 receptors, and reconstituted high-density lipoproteins [62].

Anti-inflammatory interventions under study include efforts to modulate nitric-oxide activity, therapies directed at neutrophil adhesion molecules, the infusion of antithrombin III, tissue-factor pathway inhibitors, and pentoxyfylline. Alternatively, GCSF is being studied in an effort to enhance phagocytic-cell function in patients with severe sepsis [62]. During the past 5 years, Chiron and Pharmacia's tifacogin failed late-stage clinical trials at the end of 2001 and endotoxin from Baxter/Xoma (Neuprex) has failed to show clear benefits in large-scale studies and requires extensive additional studies (2002). ICOS and Suntory, Pafase, a platelet-activating factor acetylhydrolase; Lilly's LY-315920 phospholipase A2 inhibitor; and Knoll-Abbott's monoclonal murine anti-tumor necrosis factor-alpha antibody, Afelimomab, are some recent phase III trial failures.

Despite past failures, there are still several active R&D projects in late-stage clinical trials (Box 1.5-2).

1.5.8 COST CONSTRAINTS

The start-up cost of development, manufacture, and distribution of biological products is very high, and only a few companies can manufacture and test the product to current regulatory standards of GMP, GLP, and GCP (Good Manufacturing,

BOX 1.5-2

Phase III

- Eisai Eritroran, an antagonist of lipopolysaccharide
- Takeda TAK 242, which inhibits signal transduction through Toll Like receptor 4 Phase
- Prosthetics' CytoTAb target anti-tumor necrosis factor alpha polyclonal antibody (licensed in late 2005 to Astra Zeneca)

Phase II

- Novartis (PMX 622) covalent conjugate of Polymyxin B and Dextran-70
- GSK 270773 phospholipid anti-endotoxin emulsion
- Behring Complement CI inhibitor

Phase I

- Idun (acquired by Pfizer in 2005) IDN 6556 caspase inhibitor

TABLE 1.5-12. High-priced Biologic Medications 2005–2006

Company	Trade Name	Generic Name	Indication	Price per Month $
Biogen Idec	Zevalin®	Ibritumomab	Lymphoma NHL	24,000
BMS	Erbitux®	Cetuximab	Colon Cancer	17,000
Genzyme	Fabrazyme®	Agalsidase Beta	Fabry Disease	15,000
Genzyme	Aldurazyme®	Laronidase	MPS 1	16,600

Genentech	Avastin®	Bevacizumab	Colon Cancer	4,400
Roche	Herceptin	Trastuzumab	Breast Cancer	

Laboratory, and Clinical Practice). The biologics for cancer and rare and other life-threatening diseases also rank as the most expensive treatments, and these products achieve blockbuster sales sooner than traditional pharmaceuticals (Table 1.5-12, Fig. 1.5-1). The price of biosimilar or follow-on products will be higher as compared with traditional generic drugs as very few companies can invest in manufacturing technology.

With the introduction of biologics for the treatment of rheumatoid arthritis and psoriasis, the annual cost of treatment has multiplied 10-fold to $25,000. Only about 10% of the eligible RA patients in the United States and Europe are currently on TNFα therapy. If all RA patients were to receive TNFα therapy, the total cost of therapy would reach $100 billion just for one disease only. The current or future health-care systems are not likely to fund such cost increases for anemia,

cancers, infectious, cardiac, metabolic, neurological, and rare diseases as well as increasing acute care, diagnostic, and device costs [65, 66].

Treatment of psoriasis with new biologics costs in the range of $25,000–$45,000 per year as compared with $2200 for methotrexate and $3000–$5000 per year for phototherapy. The cost of erythropoietin for renal dialysis is $10,000 per year and for cancer patients $1000 per month of treatment. New vaccines are priced in the $200–$400 range. Xigris is priced at $6800 per injection and drug-coated stents at over $3000. The European government-funded healthcare systems and insurance companies try to delay and limit access to costly new medicines and try to negotiate lower prices.

The average price of new cancer treatments and for rare diseases has increased from the $20,000–$25,000 range to the $100,000–$280,000 range per year of treatment [51–54, 66]. If two or three new drugs were to be combined for treatment of colon cancer like Eloxatin, Erbitux, and Avastin, the yearly cost could easily reach $0.5–1 million per patient. If Erbitux was used for all eligible colon cancer patients in the United States, it would cost $1.2 billion. Several European health insurance systems, oncologists, and patient organizations have raised questions about the cost–benefit ratio and called for regulatory rejection of anticancer medications with short-term limited benefits. In the future, about 80% of cancer patients will be from poor countries or without insurance coverage. Colon cancer survival doubled in the past decade, but the costs multiplied by 340 for the first 2 months of treatment [66].

The clinical testing of these high-priced drugs in poor and uneducated patients in the developing countries is problematic due to ethical and moral grounds. These drugs are not likely to be marketed in poor countries or made available to responding patients at the end of the trial. The high cost of these life-saving medicines raises several critical issues concerning access, payment, and the legal, moral, and ethical aspects of supply and demand to poor countries and patients [67, 68].

Initial reluctance and resistance by industry to reduce the prices of AIDS medications for poor countries/patients, let aside patent protection to increase supplies, or reduce prices in national emergencies like the Anthrax scare in the United States (Bayer Ciprofloxacin), SARS, and Avian Influenza (Roche Tamiflu) has eroded the image of the research-based innovative pharmaceutical industry.

Biotechnology products have so far escaped pricing pressure to reduce costs as the treatments were for life-saving or rare diseases and were marketed by big pharmaceutical firms. As biological medications prove effective in treating chronic diseases like arthritis, psoriasis, macular diseases, and diabetes, big biotechnology firms will come under pressure to reduce costs and face class-action litigation for product injury. Biotechnology industry leaders should find an appropriate balance between the current “high cost high profits, low volume” model to “affordable cost, high volume, reasonable profits” model to increase the availability of life-saving medications to poor patients and countries.

1.5.9 PUBLIC–PRIVATE PARTNERSHIPS

Several public–private partnerships support development of drugs, vaccines, and diagnostics to address diseases that predominantly afflict the poor or to make drugs

available to patients in poor countries and operate on the virtual company model [57, 69, 70]. As most pharmaceutical and biotech R&D has been directed toward diseases of the Western World, there has been no interest in developing vaccines and treatments for the tropical and neglected diseases like AIDS, Chagas' Disease, contraception, dengue, diarrhea, leprosy, leishmaniasis, lymphatic filariasis, malaria, onchocerciasis, schistosomiasis, trypanosomiasis, tuberculosis, and sexually transmitted diseases. None of the major companies has an R&D laboratory in Africa, and only two, Glaxo Smith Kline and Astra Zeneca, have R&D laboratories in Asia (outside Japan). International and national organizations like the World Health Organization (WHO) failed to develop new medications for tropical diseases and lacked sufficient resources. Universities or research institutes were not able to attract interest from the industry for promising leads, and companies terminated their own R&D leads because of lack of profits or commercial success.

Developments in the area of neglected diseases have opened up new opportunities for licensing by universities and companies. Over the past decade, private foundations and donors have provided social venture capital to launch several nonprofit "companies" that have now collectively raised over a billion dollars from philanthropic and government donors to support product development.

The price of AIDS drug tritherapy is $10,000 a year per patient in the United States and Europe. Indian companies have reduced the cost to $130 per patient per year and introduced a single tritherapy combination. When Roche was initially reluctant to increase production or reduce the price of its Tamiflu to treat Avian Influenza for developing countries claiming a difficult synthetic process, some Indian companies made the active ingredient from Shikimic acid within one week

The Foundation for the National Institutes of Health identifies and develops opportunities for innovative public–private partnerships involving industry, academia, and the philanthropic community (www.fnih.org). There were over 100 public–private partnerships funded with over $1 billion, with 60 active R&D projects for vaccines and drugs for tropical and neglected diseases by the end of 2005 (Table 1.5-13).

and new drugs under review, concerns about safety and efficacy and about prescribing information, and requirements for additional studies (http://www.fda.gov/foi/electrr.htm). Similar information is available on the Internet for public scrutiny, by the FDA/EMEA for the accepted IND files of new medications. The NIH (NIAID), Centers for Disease Control, Institute of Medicine, Mayo Clinic, Center Watch, WHO, and Public Citizen websites offer valuable information about the disease and its treatment and the list of ongoing trials. Company websites offer prescription information and other details about the currently approved drugs, clinical trials results, sales data, and R&D portfolio, patent litigation, and expenses. The commercial websites of Pharma Projects, Prous Science, Thompson, and BioCentury are other important sources for drug R&D. BiomedCentral and PubMed offer free access to many full text papers and abstracts. The ISI web of Science, Science Direct and BiomedCentral, and PubMed were consulted for reviews. To keep the number of references reasonable, original research papers have often been replaced by very recent reviews. Cochrane Reviews is a good source of new drug clinical safety and efficacy. For commercial reports, only information available in the public domain was used and cited. Negative media stories about high prices, profitability, quality/ethical problems, and links to serious adverse reactions may lead to declining sales or regulatory action.

1.5.11 INDUSTRY AND MEDICINAL BRANDS IN 2006

Most of the top companies had reported 2006 annual earnings and sales of top selling brands within the first two months of the new year. The Japanese companies had reported annual sales or forecasts based on actual results of 1–3 Q 2006, which was used. The new data was incorporated in the tables and text at the last-minute stage.

A review of the 2006 sales, market, earnings, and R&D showed several new trends and surprises in the top ten company listing as well as best selling medicinal brands [71,72]. Pfizer, which has been the most valuable company during the past five years, was overtaken by Johnson & Johnson in sales last year and briefly for a few months in market value but has now regained its top position in market valuation. Pfizer retained the top spot as the most profitable and with the highest R&D budget. Glaxo Smith Kline (GSK) retained the third position by total sales, market cap, and profitability, and topped the list with highest sales increase in 2006. Roche consolidated its return to the top ten groups by overtaking Novartis in market cap and closing the gap with Amgen in sales of biologics. Roche and Sanofi Aventis ranked second and third by sales of biologics as in 2005. Overall, increased R&D spending by the pharmaceutical and biotechnology industry failed to increase the number of new drugs approved. Only Merck and Amgen increased their R&D budget in 2006 by $1 billion over previous year. Roche, with no blockbuster going off patent in 2006, came out as the most efficient R&D company. Sanofi Aventis, despite loss of 3 blockbuster drugs to generic competition, came out second with creation and growth of several blockbuster brands. Merck and BMS ranked in the third position, while Takeda and Astra Zeneca took the fourth and fifth positions (Tables 1.5.8, 1.5.15) [71,72].

TABLE 1.5-15. Pharmaceutical Biotechnology Industry Performance Rankings 2006

Sales Increase $ Billion		Biologics Sales $ Billion		Profits $ Billion		Market Cap $ billion 7 March 2007		R&D Efficiency*
GSK	9	Amgen	14.3	Pfizer	19.3	J&J	179	Roche
Roche	5.6	Roche	13.5	J&J	14.5	Pfizer	176	Sanofi Aventis
Novartis	5	Sanofi Aventis	8.7	GSK	14.43	GSK	151	BMS, Merck
Sanofi Aventis	4.8	Novo Nordisk	7.25	Sanofi Aventis	12.6	Roche (Genentech 86)	142	Takeda
Teva	3.7	J&J	6.2	Astra Zeneca	8.54	Novartis	128	Astra Zeneca
J&J	3.3	Baxter	4.4	Roche	7.34	Sanofi Aventis	114	Abbott
Wyeth	2.4	Allergan	3.5	Novartis	7.20	Merck	96	J&J, Teva
Novo Nordisk	2.2	Wyeth	3.46	Merck	6.22	Astra Zeneca	82	Daiichi Sankyo Pfizer

Lansoprazole	3.8	Factor VIII	2.5	Remicade	0.70	Amaryl	0.29

NCE-New chemical entity; NME-New molecular entity

Several pharmaceutical companies highlighted their R&D in biologic, deals and links with biotechnology companies, and sales of biologic brands. Roche is likely to overtake Amgen in biologic sales in 2007 to emerge as the top biotechnology company. One of Roche's unit, Genentech, was the most valued biotechnology company in 2006. The big pharmaceutical companies made significant strides in biologic sales and Roche, Sanofi Aventis, Merck-Serono, J&J, and Wyeth made the list of the top ten biotechnology companies, leaving only 5 pure biotech companies in the top ten [71,72]. Teva, the world's top generic company, took the fourth position in increased net sales (Table 1.5.15).

Lipitor remains the top selling medicinal brand with $12.9 billion in sales, followed by Advair and Plavix. Rituxan, with sales of $4.7 billion, was the best selling biologic brand followed by Enbrel, Remicade, and Darbepoetin. Medicinal brands with the highest sales increase in 2006 were mostly biologic and all the brands with highest sales decline due to patent expiry and introduction of generics were synthetic chemicals. Anticancer, tumor necrosis factor inhibitors, monoclonal antibodies, and vaccines had significant sales growth. The monoclonal antibody Rituxan for cancer and arthritis emerged as the top selling biologic brand followed by TNF inhibitors (Enbrel, Remicade) and Darbepoetin, each with sales above $4 billion. All the top sales decliners in 2006 were new chemical entities in patent expiry phase in major markets. There was no biologic brand in this list. Sanofi Aventis with 3 blockbuster brands lost to patent expiry was followed by Bristol Myers Squibb and Pfizer with two each. Five top products each had sales drops of over $ 1 billion each (Table 1.5.16) [71,72].

1.5.12 CONCLUSION

R&D success has been clearly linked to the development and creation of billion-dollar human medication. Current regulations favor fast-track approval of life-saving medication and long-term safety and efficacy data for chronic diseases. The blockbuster drugs are the main driver of industrial R&D and contribute a major share of the total pharmaceutical sales, profits, and market value of the successful companies. The criteria for blockbuster drugs are defined, and output of blockbuster

drugs by pharmaceutical and biotech R&D are compared. Biotech R&D was more productive and successful than pharmaceutical R&D in creating new blockbuster brands. The current Gold Rush of biologics indicates a paradigm shift in innovation from pharmaceutical to biotechnology R&D. Another perceptible shift is the industrial R&D bail-out from Europe toward the United States, once again based on the success of the U.S. biomedical science and biotechnology firms. Biotechnology R&D success includes several blockbuster brands of erythropoietin, tumor necrosis factor alpha blockers, insulin, interferon, and GCSF, monoclonal antibodies, vaccines, and anticancer, which had sales of over $1 billion during the 2004–2006 period. Biotechnology R&D failure includes Alzheimer's Disease, sepsis, and vaccines for RSV, malaria, and AIDS. Several public–private partnerships, operating on the virtual drug development company model, have taken up the void left by industry bail-out of tropical and neglected diseases. The high cost of biologics and link to serious adverse reactions will become important as biologics are used to treat chronic conditions like rheumatoid arthritis and psoriasis. New and old media have played an important role in raising awareness about new blockbuster biologics brands.

There were no indications or signs during the past 3 years from the big consultancy firms predicting the "End of the Blockbuster Era." On the contrary, the number of blockbuster brands has shown steady and continuous growth and now accounts for a major share of market, sales, and profits of the pharmaceutical and biotechnology industry. Pharmaceutical companies' outright acquisition of biotechnology companies and the licensing of technology/late stage projects in development increased significantly. The market and sales data once again provide strong support for the R&D paradigm shift to biologics and within biologics towards human monoclonal antibodies with a message: "It's biologics, Stupid."

ACKNOWLEDGMENT

The author wishes to thank the following persons for their review and critical comments on the draft: Dr. Daniel Brandt, Debiopharm, Lausanne; Mr. Mohammad Akram, Business Consultant, Geneva; and my wife Dr. Sunita Maggon for editing, data collection, and literature search. I wish to thank Mr. Robert Posey (PDP, Geneva) for providing office facilities and administrative support.

2.1 INTRODUCTION

Over the last three decades, the scientific efforts mainly focused on molecular biology, genetics, recombinant DNA (rDNA) technology, and lastly genomics and

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

bioinformatics have had a huge impact on our understanding of disease pathophysiology and of drug actions at the molecular level. In addition, the accumulated genomic knowledge has provided the ability to predict drug–drug interactions and the emergence of adverse drug reactions (ADRs) in clinical practice, a fact of great importance in modern pharmacology and therapeutics. The elucidation of specific clinical- as well as genetic-related factors predisposing to individual drug–drug interactions, ADRs, or drug disposition also gives new dimensions to new drug development and pharmacotherapy [1–5]. Furthermore, the evolution of genomic technologies offered new tools for extracting drug-related information especially through the emergence of pharmacogenomics in recent years [6–9] (for term definition in pharmacogenetics, pharmacogenomics, and other drug-related areas, see the website: http://www.genomicglossaries.com/). Pharmacogenomics aims to strengthen drug efficacy and to prevent most, if not all, ADRs from emerging during pharmacotherapy. Furthermore, pharmacogenomics provides the methodology and the knowledge to medical practitioners to genetically test each patient before the administration of the drug of interest, a practice that obviously can lead to personalized drug therapy. To this end, improved pharmacotherapy outcomes are expected by anticipating and minimizing toxicity related to drug delivery in everyday patient care. By integrating the genomic drug-related data into drug delivery, pharmacogenomics is moving toward the application of pharmacotyping in drug prescriptions, where clinical and genomic information will be used to ensure maximum efficacy and safety in clinical practice, as it has been recently proposed [10].

Interestingly, this is happening in parallel with the efforts focusing on the creation and establishment of unified information-based platforms in medicine, a fact that obviously will accelerate the technological advancement for the integration of genomic data in clinical practice. The latter has been recently facilitated through the technological developments that now allow the application of molecular diagnostics and devices at the nanoscale level. Such a direction, however, stresses the need for a multidisciplinary approach in future health care by permitting nanomedicine to apply molecular diagnostics and new innovative drugs in a way that is beneficial in routine medical practice both in disease diagnosis and in therapeutics. This is a major advantage, because the development of nanotools is in high demand in information-based medicine and the application of suitable platforms for the exploitation of genomic information in medicine and pharmacy. Thus, the intercorrelation of the molecular knowledge extracted from the clinical, genomic, and technological health-related areas as well as the transformation into a form readily applicable in health care can be achieved. As a matter of fact, the evolvement of nanomedine seems to go in parallel with the capability of genomic technologies to transform medicine and pharmacy, and in this regard, their use depends on well- and properly educated practitioners able to work in a well-organized and information-based clinical infrastructure. Collectively, this approach in pharmacotherapy belongs to the broader concept of personalized medicine because its major goals are considered the anticipation and minimization of the individual risk of disease onset and progression as well as the individualized drug therapy for improved patient care [11].

Overall, by using the principles of pharmacogenomics, personalized medicine, and pharmacotyping in patient care, and by monitoring their impact on current drug development and delivery, a major benefit is expected upon co-evaluation of

genomic with clinical data to improve pharmacotherapy outcomes. In this regard, the clinical validation of genomic data for routine drug prescription, the training of future health-care professionals, and the integration of molecular medicine into clinical trials for new drug development have to be defined and clearly addressed. Also, the need for extensive discussions about the ethical, societal, and economic impacts arising from the application and use of genomic data in patient care is now, more than ever, a necessity. The latter stresses the need for the proper education of health-care professionals in order for them to actively be involved in, and positively influence, all these issues in health care. The experience already gained has shown that this can be achieved in the near future, because the first pharmacogenomics test (AmpliChip Cytochrome P450) approved by the U.S. Food and Drug Administration (FDA), recently, to improve the delivery of drugs that are substrates or inhibitors of cytochrome P450 (CYP)2D6 and/or CYP2C19 has been introduced in everyday clinical use. Also, recently released on March 22, 2005 by the FDA, the guidelines for industry concerning the submission of pharmacogenomics data upon the process of application of new drug development, a fact expected to have a major impact on the flow and generation of data in clinical pharmacogenomics and the application of pharmacotyping in drug prescription. This means that the detection of single nucleotide polymorphisms (SNPs) or other genetic variations and the establishment of specific genotypes and haplotypes for several genes must be first defined and clinically validated at such a level as to explain why one patient responds well in drug therapy, another does not, or even another experiences serious ADRs. In fact, this will be a major transition in pharmacotherapy because pharmacotyping will be finally achieved, and, to this end, the medical practitioner in collaboration with other specialties will also be based on patient's genotyping–haplotyping analysis data for initiating and maintaining drug dosage therapeutic profiles for individual patients [5, 10]. However, in order for these new directions in therapeutics to succeed with maximum benefits to patients and society, the future advances in pharmacogenomics and bioinformatics have to first allow the smooth digital integration and second the easy end-user utilization of genomic and clinical data in unified information-based platforms within the healthcare system.

2.2 PHARMACOGENOMICS AND PHARMACOTYPING FOR COMPLEX AND POLYGENIC DISEASES

The concept of ensuring maximum efficacy and safety upon drug delivery is the long-desirable target of pharmaceutical care that implies improved pharmacotherapy profiles and outcomes in clinical practice and coincides chronologically with the establishment of pharmacology as a basic and clinical discipline. Also, the ability to lower the incidence of drug toxicity and the emergence of ADRs is a fundamental issue for the empowerment of health care in terms of patient's quality of life and cost (Box 2.1). Nowadays, this situation in pharmacotherapy has been, more or less, closer to reality. This happens due to the rapid development of genomic and information-based technologies and their application in pharmacotherapy and clinical practice (Figure 2-1). For example, it is now well accepted that, in terms of drug toxicity, many ADRs arise because of inter-individual genetic differences in drug metabolizing enzymes, drug transporters, ion channels,

BOX 2.1 MAJOR POINTS RAISED IN HEALTH CARE UPON THE INCIDENCE AND THE SEVERITY OF ADRS IN CLINICAL PRACTICE

- In a meta-analysis from 39 prospective studies in U.S. hospitals, it has been proposed that 6.7% of hospitalized patients developed ADRs during pharmacotherapy and 0.32% showed fatal ADRs, the latter causing about 100,000 deaths per year in the United States [12].
- The report released from the Institute of Medicine in December 1999 has shown that nearly 98,000 deaths in the United States annually were attributed to medication errors including ADRs [13].
- Furthermore, 10–17% of patient hospitalizations are directly related to the emergence of ADRs, an effect that poses patient pharmaceutical care and safety as a fundamental issue in each healthcare system [14].
- It has been estimated in the United States that the cost attributed to the emergence of ADRs is approximately $100 billion, a fact that further stresses for the improvement of drug delivery in clinical practice [15].
- In a 2-year period of study conducted in by the Department of Internal Medicine in a Norwegian hospital and from 732 deaths reported amongt the 13,993 in-patients, 133 of them were directly attributed to ADRs observed during pharmacotherapy [16]. This result gives almost 10 deaths per 1000 hospitalized patients, a number that urgently demands an improvement of drug delivery by strengthening drug efficacy and minimizing toxicity in the healthcare system.
- It has also been estimated that about 7% of all hospital admissions in the United Kingdom and Sweden are due to ADRs developed in clinical practice [15].

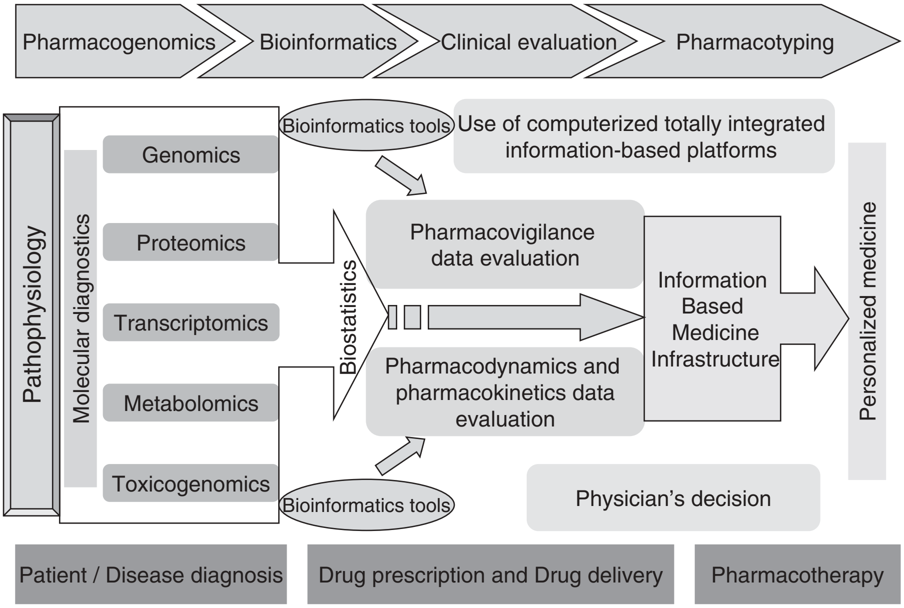

Figure 2-1. Pharmacotyping and information-based medicine in postgenomic drug delivery and health care (see the text for details).

receptors, and other drug targets [1, 2, 5, 10, 17, 18]. Furthermore, several pharmacogenomics studies have revealed various examples of clinically relevant genetic polymorphisms that are associated with altered drug response in patient care. Representative examples of such polymorphic gene variants of pharmacogenomics relevance are shown in Box 2.2. Although these intriguing data are very interesting in trying to understand the correlation between genetic make-up and various drug effects in the body, much work is needed for this type of drug-related genomic information to be transformed, integrated in everyday clinical practice, and, finally be available on a broader basis in health care.

Through the sophisticated technological advances achieved thus far, the genomic knowledge is entering clinical practice and being used to analyze complex diseases including cardiovascular diseases, asthma, cancer, and degenerated disorders [38–42]. Furthermore, the broad use of automated DNA sequencing techniques and the application of DNA microarray (DNA chip) systems permit the rapid and reliable assessment of a large number of genes implicated in drug response and/or disease phathogenesis [43–45]. Alternatively, and of equal importance, specific gene variants have been found either to predispose for, to contribute to, or even to increase the susceptibility of individual persons for disease development and progression. Unanimously, the availability of DNA microarray technology helped genomics research to achieve widespread interest particularly in clinical sciences and pharmacotherapy. As a matter of fact, it is a valuable technique for the improvement of clinical diagnosis and the understanding of molecular etiology and pathophysiology of polygenic and multifactorial conditions, e.g., cardiovascular diseases and degenerating disorders, because it gives researchers the ability to assess and evaluate each time the expression of nearly all genes presented in the human genome. For example, there have been several attempts, in the past few years, to establish specific polymorphic gene variants at pharmacodynamic loci predisposing to cardiovascular diseases or to affect drug response such as angiotensin-converting enzyme (ACE), angiotensin II type-1 receptor (AT-1), apolipoprotein E (APOE), α-adducin, and adrenergic receptors that could alternatively be used to improve the pharmacotherapy profiles of drugs exerting their effects through binding to these receptors [46–49]. It is also very interesting for anyone to see now, that genomic studies, throughout the last period of 10–15 years, have revealed several chromosomal loci and genes implicated for example in cardiomyopathies, arrhythmias, heart failure, and hypertension. The identification of several genes whose function is associated with diseases like hypertrophic or dilated cardiomyopathy, human long-QT syndrome, and essential hypertension give new insights on a molecular basis to heart disease progression and may help in orienting the proper drug therapies in a given population. Among them are included genes encoded for β-myosin heavy-chain, cardiac troponins and α-tropomyosin in hypertrophic cardiomyopathy; dystrophin, tafazzin, and actin in dilated cardiomyopathy; cardiac sodium channel (SCN5A) and potassium channel (HERG) in long-QT syndrome; as well as ACE, α-adducin, angiotensinogen, and β_2-adrenergic receptor (β_2AR) in essential hypertension [33, 39, 50]. Furthermore, even more impressive is the fact that, in the case of cardiomyopathies, genomic analysis has been able to establish specific molecular gene expression profiles that clearly define different molecular classes of cardiomyopathy such as of sarcomyopathy, cytoskeletalopathy, and cytokinopathy [51–54]. However, although these represent intriguing results in genomic

BOX 2.2 GENETIC POLYMORPHISMS IN SPECIFIC GENES ASSOCIATED WITH VARIOUS DRUG RESPONSE AND EMERGENCE OF ADRS IN CLINICAL PRACTICE*

Genetic polymorphisms of pharmacogenomics importance that can modulate the pharmacological response of specific drugs implicate the following genes:

1) *CYP2C9* that has been implicated in warfarin, phenytoin, tolbutamide, and/or glipizide has had various clinical responses [1].
2) *CYP2C19* that has been involved in proton pump inhibitors (e.g., omeprazole) has had an altered clinical response [19].
3) *ABCB1* gene that has been associated with the development of molecular resistance of anti-epileptic drugs [20, 21].
4) UDP-glucuronosyltransferase 1A1 (*UGT1A1*) that has been involved in irinotecan toxicity [20, 22].
5) Human leukocyte antigen (*HLA-B*) that has been associated with abacavir hypersensitivity [23, 24].
6) Glutathione-S-transferases (*GSTs*) that have been correlated with platinum chemotherapeutic agents and D-penicillamine altered response [25, 26].
7) N-acetyltransferases (*NATs*) that have been implicated with the emergence of sulfonamides hypersensitivity and the toxicity observed in some cases of isoniazid, procainamide, and hydralazine administration [27].
8) HERG potassium channel (*KCNH2*) that has been found to modulate quinidine and/or cisapride safety in clinical practice as well as KvLQT1 potassium channel (*KCNQ1*) that causes a similar effect on terfenadine and disopyramide response [28, 29].
9) Thiopurine methyltransferase (TPMT) activity has been well correlated with 6-mercaptopurine, 6-thioguanine, and azathioprine toxicity seen in some patients [1, 30, 31].
10) Several genetic polymorphisms of serotonin *5-HT2A* and *2C* receptors have been implicated with various pharmacological responses to clozapin delivery [32].
11) The angiotensin II type I-receptor (*AT-1*) gene has been associated with the altered drug response of losartan seen in certain patients [33].
12) The apolipoprotein E4 (*APOE4*) allele has been correlated with the variability of tacrine pharmacotherapy [34].
13) The gene of 5-lipoxygenase (*ALOX5*) has been studied in relation to zileuton and montelukast altered drug response [28].
14) Several genetic polymorphisms of β_2-adrenergic receptors (β_2*AR*) have been shown to modulate the β_2-agonist (e.g., albuterol) effect in clinical practice [35, 36].
15) The ABCG2 transporter gene, a member of the ATP-binding cassette transporters, in which an Arg to Gly mutation at amino acid 482 (G482 mutation) has been shown to confer high-level resistance to various antifolate chemotherapeutic agents [37].

* Modified from Ref. 5.

medicine, the recognition of the complexity of such diseases clearly demands the development and clinical validation of suitable genetic diagnostic markers; the application and use of more sophisticated, clinically validated genomic and bioinformatic tools; as well as the design of prospective pharmacogenomics studies, in order to further advance the molecular understanding of the disease pathophysiology and to improve the therapeutic intervention in clinical practice.

Regarding the degenerating diseases, the structural and functional genomics analysis of patients with Alzheimer's disease (AD) has recently identified several genetic loci that potentially contribute to disease pathophysiology in cooperation with both environmental and epigenetic factors [40]. In particular, genetic predisposition to AD development is demonstrated either for genes whose variants exhibit a mendelian inheritance pattern, e.g., the amyloid precursor protein (APP), and the presenilin-1 (PS1) and -2 (PS2), or for those considered to be potential susceptibility genes contributing to AD predisposition, e.g., APOE, ACE, interleukin-1α (IL1α), nitric oxide syntase-3 (NOS3), low-density lipoprotein-related protein 1 (LRP1), and α-2-macroglobulin (A2M). Furthermore, recent results have suggested that specific genotypes and haplotypes may cause different drug response rates in individual AD patients receiving cholinesterase inhibitors and/or noncholinergic agents used for their therapeutic intervention [34, 40]. This progress in AD genomics clearly shows that pharmacogenomics analysis of complex and polygenic disorders has started to give valuable clinical results. As a matter of fact, the broader application of pharmacogenomics can be an alternative and suitable platform for further assessing the pathophysiology and molecular diagnosis of complex diseases, as well as for the identification of new drug targets to improve healthcare outcomes and patient's quality of life. To this end, however, as in the case of cardiovascular diseases, the establishment of clinically validated specific molecular diagnostic biomarkers and pharmacotyping profiles for individual patients is still a demand, in order for these efforts to be finally achieved in clinical practice.

2.3 PHARMACOTYPING CONCEPTS AND CYP-MEDIATED METABOLISM OF DRUGS

By considering the example of CYPs that are involved in the phase I drug metabolism in the body, the importance of pharmacogenomics studies and their clinical relevance in drug disposition will be further defined. Nowadays, 57 putative functional genes encoding different CYP enzymes and 58 pseudogenes have been characterized [55, 56] (see also the website: http://drnelson.utmem.edu/CytochromeP450.html). The major human CYP enzymes involved in drug metabolism include CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4, and CYP3A5 that exhibit several polymorphic sites of clinical significance (see the website: http://www.imm.ki.se/cypalleles). Indeed, several experimental studies of applied pharmacogenomics research have already been published that correlate specific CYP gene variants with altered drug efficacy and safety and clearly shed light on the elucidation of the molecular mechanisms involved in inter-individual drug response observed among patients suffering from the same disease. The existed complexity at the genomic level in drug metabolism is additionally complicated by considering the high number of polymorphic gene

variants encoding CYP enzymes discovered, especially those belonging into CYP families 1, 2, and 3. It has been estimated that enzymes belonging to these families mediate about 70–80% of all phase I-dependent metabolism of clinically used drugs. Interestingly, polymorphic enzymes that mainly account for ~40% of CYP-mediated drug metabolism are those of CYP2C9, CYP2C19, and CYP2D6 and, for this reason, are considered very important in pharmacotherapy by making problematic the application of a general drug dosing scheme for the drugs whose disposition is determined by these enzymes [15]. Similarly, by evaluating the incidence of ADRs, it has been shown that ~56% of drugs cited in ADR-related studies are metabolized by polymorphic enzymes of phase I, in which ~86% account for the CYP-mediated metabolism. On the contrary, only 20% of drugs that are substrates of non-polymorphic enzymes are cited in the ADRs reports [15, 57].

It is now well known that the genetic variability observed in CYP enzymes corresponds into four phenotypes of clinical relevance in drug delivery. The definitions used to identify these four phenotypes of CYP-related drug metabolism are as follows:

1. Poor metabolizers (PMs) for those individuals that have shown no enzymatic activity in diagnostic tests. Therefore, this is a phenotype that refers to people who lack the functional CYP enzyme and slowly metabolize the drug substrates, allowing their concentration to reach high plasma levels.
2. Intermediary metabolizers (IMs) for those individuals with reduced enzymatic activity. These people are heterozygous for one deficient allele or carry two alleles that cause lower CYP enzyme activity.
3. Extensive metabolizers (EMs) for individuals with physiological enzymatic activity, a fact that suggests the existence of two wild-type (normal) alleles allowing normal drug metabolism.
4. Ultrarapid metabolizers (UMs) for individuals having higher than normal enzymatic activity. Therefore, this is the phenotype applied to people carrying multiple gene copies of the respected enzyme. That trait is dominantly inherited and allows these individuals to rapidly metabolize the drug substrates and to achieve low, and sometimes inefficient, plasma levels.

Several examples of drugs whose dosage is related to CYP phenotypes have already been reported that further envisage on the importance of CYP polymorphisms for routine drug prescription and the modulation of pharmacotherapy outcomes. For example, CYP2D6 and CYP2C19 are responsible for the metabolism of most psychoactive drugs, including antidepressants. In particular, specific dosage recommendations for patients with EM, IM, and/or PM phenotypes of either CYP2D6 or CYP2C19 have been suggested for 14 antidepressant drugs [58]. Furthermore, the kinetics of nortriptyline is dependent on the number of active CYP2D6 genes, and the dosage required to reach the same plasma levels varies from 30–50 mg in CYP2D6 PMs to 500 mg in UMs [15]. Another example applies to sertraline, a substrate of CYP2C19 (and an inhibitor of CYP2D6), because CYP2C19 PMs develop ADRs (nausea and dizziness), a fact that might be attributed to increased sertraline plasma concentrations. In addition, the metabolism of valproate (commonly used to treat bipolar disorders) has been found to be influenced by CYP2C9

polymorphism, an effect of clinical relevance. Thus, the broader application of CYP-related pharmacogenomics knowledge to implement clinical experience can improve pharmacotherapy outcomes through the establishment of individualized dosage-regimens that take the difference in drug metabolic capacity into account.

Similarly, the fundamental role of CYP-related knowledge in minimizing the incidence of drug–drug interactions in clinical pharmacology and the application of such information in improving pharmacotherapy outcomes is now well appreciated in drug delivery and can be further defined by the example of cholinesterase inhibitors (rivastigmine, tacrine, donepezil, and galantamine), which are agents used to treat symptoms of patients suffering from AD. By assessing the drug–drug interactions of this group of agents published in several clinical studies, it can be suggested that the individual CYP-isoform implicated in the metabolism of each cholinesterase inhibitor also specifies the type of interacting drugs referred to modulate its pharmacokinetic parameters and clinical outcome [59, 60]. In particular, because the metabolism of rivastigmine is mediated predominantly by esterases rather than by hepatic CYP enzymes, clinically relevant drug interactions implicated by this phenomenon are unlikely. This fact for rivastigmine was indeed verified by *in vitro* assays and pharmacokinetic studies conducted in humans. To this regard, in a retrospective analysis including four major clinical trials with 2459 patients, it has been shown that no increase in adverse events occurred among those patients who received 22 different therapeutic classes of drugs commonly used in elderly populations, including antihypertensive, anti-histamine, anti-inflammatory, or anxiolytic agents [59].

Tacrine is primarily metabolized by the hepatic CYP1A2 (and to some extent by CYP2D6), so substrates, inhibitors, or inducers mainly of CYP1A2 are expected to alter its bioavailability. This is indeed the case: (1) with fluvoxamine (50 or 100 mg/day), which is a potent CYP1A2 inhibitor that caused ~85% reduction of tacrine metabolism; (2) with cimetidine, also a CYP1A2 inhibitor, where it has been observed that plasma concentrations of tacrine were increased by ~30%, so a reduction of its dosage has been advised when co-administered with cimetidine; (3) with estradiol also metabolized by CYP1A2 that caused an increase of ~60% in AUC and of ~46% in the mean C_{max} of tacrine. Following these data, it has also been reported that tacrine decreased by ~50% the clearance of theophylline, which is also a substrate of CYP1A2, so reduction of theophylline dosage has been suggested upon its co-administration with tacrine. In addition, tobacco smoking that induces CYP1A2 metabolism significantly accelerates tacrine metabolism, a result indicating that clinicians should be aware that smokers may require higher doses of tacrine than that would be given to nonsmokers [60].

Similarly, in the case of donepezil that is primarily metabolized by the hepatic CYP3A4 and CYP2D6, it is expected that substrates, inhibitors, or inducers of CYP3A4 and of CYP2D6 can alter its bioavailability. This prediction is indeed verified in certain pharmacotherapy dosage regimens: (1) with ketoconazole (200 mg/day), a potent inhibitor of CYP3A4, where a significant increase (23–30% at steady state) in the plasma concentrations of donepezil was observed; and (2) with paroxetine and sertraline, which are both of them CYP2D6 inhibitors, in which a careful patient monitoring has been recommended upon co-administration, due to possible interaction of donepezil with these drugs through inhibition of CYP2D6. On the contrary, upon the delivery of donepezil with

risperidone and/or thioridazine, the latter two are substrates, but not inhibitors, of CYP2D6, and no significant interaction was observed. The same has been shown with digoxin (no significant CYP metabolism), theophylline (substrate of CYP1A2), warfarin (substrate of CYP2C9), and/or cimetidine (inhibitor of CYP1A2 and CYP2C19) [60].

By proceeding through the analysis to galantamine, similar results have been obtained. Galantamine is also metabolized by CYP3A4 and CYP2D6, so again the potent inhibitors of these isoenzymes are expected to result in significant drug–drug interactions. Such interaction was indeed observed: (1) with paroxetine (an inhibitor of CYP2D6 and CYP2C19) that caused an increase in the bioavailability of galantamine by 40%, as it has been reported upon their co-administration; and (2) with ketoconazole (an inhibitor of CYP3A4 and CYP2C19) that exerted a significant increase in the bioavailability of galantamine by 40%. However, no significant interaction of galantamine with warfarin and digoxin has been observed in clinical studies [60].

The above-mentioned example of cholinesterase inhibitors clearly shows the predictive value of CYP-related information during everyday drug prescription, because the avoidance of co-administration of drugs implicated with the same CYP isoform can ultimately improve pharmacotherapy outcomes, at least for drugs whose metabolism is the rate-limiting step upon the establishment of their therapeutic concentrations in the body. However, and more importantly, this knowledge has already started to implement routine clinical practice, since the first pharmacogenomics test was approved by the FDA on December 23, 2004. The "AmpliChip Cytochrome P450 Genotyping test" permits the identification of 31 different polymorphisms of CYP2D6 (29 polymorphisms) and CYP2C19 (2 polymorphisms), and it is used along with clinical evaluation and other tools to determine the best treatment options for patients taking drugs that are either substrates or inhibitors of these metabolizing enzymes. The development of this test is of great importance in pharmacotherapy, because it represents the first step toward the broader application of pharmacotyping concepts in drug prescription.

2.4 PHARMACOTYPING CONCEPTS FOR MODULATING THE PHARMACODYNAMICS AND PHARMACOKINETICS OF DRUGS

Interestingly, and in addition to CYP gene variants already mentioned in the previous section, specific genetic polymorphisms were also analyzed in genes encoding P-glycoprotein (P-gp), G-protein coupled receptors (GPCRs), thiopurine methyltransferase (TPMT), ACE, arylamine N-acetyltransferases (NATs), and/or UDP-glucuronosyltransferases (UGTs), just to mention a few, which have also been shown to correlate with altered drug response and incidence of ADRs in humans [20,22, 27, 30, 35, 46, 61–63], (see also Box 2.2). To better clarify the correlation of such gene variants with the pharmacotherapy outcome, experimental data related to either the ABC-type transporters function or to the variability of anti-asthmatic drug delivery will be discussed. P-gp is an ATP-dependent transporter (efflux pump) belonging to the superfamily of ABC transporters that includes 48 already identified members in humans. The role of P-gp in limiting intestinal, brain, and placental transport, as well as in biliary and urinary excretion of its substrates, is

now well recognized. Thus, variations in its gene (*ABCB1* or *MDR1*) that existed in several individuals may influence drug disposition and alter drug response [20, 63]. These genetic variations can affect the function of P-gp as transporter by altering its binding with drugs and other xenobiotics [20]. Confirmatory to this notion is the mutant variant of *ABCB1* designated as ABCB1-C3435T, which has been characterized recently and has been shown to be well associated with the variability of antiepileptic drug response [21]. At the same time, further functional characterization of specific P-gp gene variants, or other ABC-type transporters, and elucidation of the molecular mechanisms that underlined their involvement in interindividual drug variability are expected to give new insights into the selective modulation of the P-gp function in the blood-brain barrier for optimizing therapeutic intervention and improving patient pharmaceutical care [64]. The clinical relevance of the mutant alleles of ABC-type transporters in pharmacotherapy was further confirmed in another member of this class. Recent studies have established that an Arg to Gly mutation at amino acid 482 (G482 mutation) in the ABCG2 transporter confers high-level resistance to various antifolate chemotherapeutic agents (e.g., methotrexate) [37].

Nowadays, specific polymorphisms in individual genes have been studied to explain the variability seen upon anti-asthmatic drug delivery, like β_2-agonists (see also Box 2.2). For example, it has been estimated that as much as 60% of interindividual variability in anti-asthmatic drug response observed with β_2-agonist delivery might involve genetic factors modulating the pharmacotherapy outcome [35]. Thirteen SNPs identified in the promoter and the coding region of β_2AR gene were found to be organized into 12 haplotypes. Some of these haplotypes have shown significant divergence in different ethnic populations, and this fact is associated with the bronchodilator response to β_2-agonists in patients with asthma [36]. As asthma is considered a complex and polygenic disease, several other gene variants have also been shown to contribute to the pharmacotherapy outcome in asthmatics in addition to β_2*AR* polymorphisms. Such genes include those of 5-lipoxygenase (*ALOX5*) for zileuton, muscarinic receptor-2 (M_2) and 3 (M_3) for muscarinic antagonists (e.g., ipratropium bromide), glucocorticoids receptor for glucocordicoids (e.g., prednisolone, beclomethasone), and phosphodiesterase-4A (*PDE4A*) and 4D (*PDE4D*) for theophylline delivery [65]. However, although these correlations add valuable knowledge to basic and clinical pharmacology, more systematic efforts at the molecular level must be undertaken toward thorough elucidation of the underlined mechanisms of genetic drug response variability, in order for the anti-asthmatic therapy and outcome to be finally enriched and improved.

2.5 CANCER PHARMACOGENOMICS AND PHARMACOTYPING

Recent progress in cancer pharmacogenomics suggests that improvement of chemotherapy outcomes for specific anticancer drugs, like 5-fluorouracil (5-FU), irinotecan, platinum agents, and thiopurine-like drugs, can be achieved. In particular, specific polymorphisms in genes encoding the enzymes dihydropyrimidine dehydrogenase and thymidylate synthase have been shown to influence the efficacy and toxicity of 5-FU in certain individuals. The applicability, however, of such an approach by selecting patients who are likely to tolerate and respond to 5-FU

therapy remains very complicated, and it is not easily attainable for everyday care [20, 66]. Furthermore, it has been proposed that polymorphisms in the promoter region of the gene encoded UDP-glucuronosyltransferase 1A1 (*UGT1A1*) may be clinically useful for predicting severe patients' toxicity to irinotecan, thus making this drug an excellent candidate for individualized therapy, as it has been recently proposed [67]. Irinotecan belongs to the camptothecin class of topoisomerase I inhibitors and has been shown to have potent activity against many types of solid human tumors, in particular, gastrointestinal and pulmonary malignancies [22, 67]. It is a prodrug that is converted in the body by carboxyesterase-2 to SN-38 metabolite with more than 1000-fold enhancement of cytotoxic activity. The rate-limiting step of SN-38 pharmacokinetics is considered the UGT glucuronidation reaction *via* hepatic UGT1A1, whereas the presence of the homozygous *UCT1A1*28* genotype in patients as a molecular predictor of toxicity risk (the promoter region contains seven TA repeats instead of six in the normal wild-type genotype) seems to be associated with high risk of grade 4 neutropenia in clinical practice [67]. The predictive value of the *UCT1A1*28* genotype, in order clinicians to address more definitive guidelines regarding the effective and safe dose of irinotecan in these patients, however, remains to be established.

Also, in the case of platinum chemotherapeutic agents (cisplatin, carboplatin, and oxaliplatin), several polymorphic genes have been implicated in their efficacy and toxicity. These genes are the *XPD* and *XRCC1* that encode proteins involved in the cellular DNA excision repair system and that of glutathione-S-transferases (GSTs) [66]. Although these results can be con-sidered as positive indicators for the improvement of cancer patient care, additional work must be done in order for the general applicability and acceptance of genetic information related to platinum agents response to be established in clinical practice.

However, one of the most studied examples of applied pharmacogenomics that clearly shows how the translation of genomic information is being transferred to guide patient therapeutics is related to TPMT gene polymorphisms. Interestingly, specific TPMT gene variants have been isolated and clinically validated in studies showing that their presence is associated with high-risk toxicity in individuals taking thiopurine drugs (6-mercaptopurine, 6-thioguanine, azathioprine) [30, 31, 68]. Currently, eight TPMT alleles have been identified, including three variant alleles designated as TPMT*2 (with G238C mutation), TPMT*3A (with G460A and A719G mutations), and TPMT*3C (with A719G mutation) that account for about 80–95% of intermediate or low TPMT enzymatic activity, and for this reason, they are analyzed during genotyping and haplotyping population studies [30]. The pharmacogenomics data regarding the TPMT deficiency correlated well with thiopurine drug toxicity and were so clear and convincing that a TPMT genetic test was developed for clinical use before the initiation of 6-mercaptopurine delivery to children suffering from acute lymphoblastic leukemia (ALL) [69, 70]. The clinical usefulness of this genetic test was based on pharmacogenomics data suggesting that the calculation of a drug dosage scheme could be achieved though the identification of the specific TPMT genotype in each child. However, the difficulty of applying the genetic test in clinical practice was further demonstrated by the discussions after the attempts to apply TPMT pharmacogenomics data upon thiopurine drug prescription. Such discussions have been extended even to the need and usefulness of the genetic testing as compared with the traditional biochemical tests,

e.g., the use of a red-cell assay for the detection of TPMT enzyme deficiency [11, 70]. The example of a TPMT genetic test clearly shows the difficulties that these new concepts of drug delivery will meet before their general acceptance in routine everyday use. Undoubtedly, to ascertain for applied pharmacogenomics a final success, more systematic work and advancement in information-based technologies are needed. In turn, this will allow better transformation of genomic data into clinical forms to finally lead into the wide use of genetic testing with high-quality and validity outcomes, thus ensuring specific dosage recommendations of individual drugs in routine pharmaceutical care [71, 72].

Of special interest, however, related to the application of pharmacotyping in anticancer therapeutics are issues concerning the development of drug resistance, as this phenomenon consistently affects the pharmacotherapy outcomes and patient's quality of life. Over the past several years, novel exploitable targets for cancer drug development have been revealed that recently resulted in the development of some innovative drugs already applied to clinical practice. Such targets include enzymes like tyrosine kinases involved in signal transduction pathways, genes regulating apoptosis and differentiation of malignant cells, cell-lineage transcriptional factors, angiogenesis factors, and unique proteins driving the cell cycle machinery [73–78].

The development of imatinib (Gleevec) as an effective agent capable of inducing cellular apoptosis for the treatment of patients suffering from chronic myelogenous leukemia (CML) represents such a bright example of molecularly targeted anticancer therapeutics [79]. Gleevec is a selective inhibitor of Bcr-Abl fusion tyrosine kinase specifically present in CML patients that results from a reciprocal translocation between chromosomes 9 and 22. This translocation causes the genetic fusion of *bcr* with exon-1 of *c-abl* resulting in a defect known as Philadelphia chromosome. Although the use of imatinib give very impressive and promising results for the therapy of CML as well as for other tumors by also inhibiting the c-kit kinase, the development of drug resistance causes a real restriction point into its clinical use for all CML patients [80]. This restriction is partially attributed to the occurrence of specific mutations in the gene encoding the Bcr-Abl fusion tyrosine kinase, a result that poses the drug resistance development of major concern in modern cancer pharmacotherapy.

The difficulties in reaching improved pharmacotherapy outcomes have also been reported upon the clinical use of gefitinib (Iressa) developed for solid tumor therapeutic intervention, which has had limited, success. This agent, indeed, has been shown to be effective and beneficial only in non-small cell lung cancer (NSCLC) patients whose tumor cells exhibit mutations in the epidermal growth factor receptor (EGFR) gene leading to activated forms of the extracellular domain of EGFR kinase [81–84]. Furthermore, the failure of gefitinib to prolong patient's lives limited its use in the United States during 2005, whereas at the same time caused a withdrawal of its marketing application in Europe [85]. This effect, however, has not been seen in the case of erlotinib (Tarceva), which is another EGFR tyrosine kinase inhibitor in clinical use, where a survival benefit in lung cancer patients has been measured in prospective clinical studies. At the same time, discussions regarding the development of multitargeted tyrosine kinase inhibitors to overcome the limited efficiency of gefitinib, like zactima that inhibits both tyrosine kinases of EGFR and vascular endothelial growth factor (VEGF) receptor-2, have sparked

new research efforts in the field of developing tyrosine kinase inhibitors as new anticancer drugs. Overall, the experience already gained from the development and use in clinical practice of drugs of the new class of tyrosine kinase inhibitors (imatinib/Gleevec; gefitinib/Iressa; erlotinib/Tarceva) has clearly shown that the path from the initial enthusiasm of innovative drug discovery to improving pharmacotherapy outcomes *via* the identification of the molecular basis of responders and nonresponders has not been straightforward and easily attainable [77].

The problems confronted in clinical practice upon the delivery of tyrosine kinase inhibitors as drugs obviously support the notion for the exploitation of alternative and more sophisticated ways that must be undertaken in order to better cure cancer patients. Also, it stresses the need for thorough understanding of the molecular mechanisms that underline vital cellular processes before pharmacotyping can be generally applied in clinical practice. To this end, and to avoid such undesirable effects, the development and use of drugs that can induce simultaneously differentiation and apoptosis of leukemia cells have also been suggested [78]. Both processes result in restricted cell growth and thus represent a desirable target for the development of new anticancer therapeutics. To this end, the process of cell renewal in leukemia versus that of cell differentiation and/or apoptosis seems to be linked somehow to each other, thus giving hope that both differentiation and apoptosis can be simultaneously activated in order to serve as potential platforms for developing combined therapeutic approaches [78, 86, 87]. Toward this direction, the use of model cellular systems for more detailed analysis of the function of genes and the elucidation of their specific interactions in normal and disease states represents a useful alternative experimental design of clinical significance, as it has been recently shown [78, 87].

Interestingly, great progress has recently occurred in breast cancer biology and pharmacotherapy by revealing the structural interactions of the drug Herceptin and its receptor HER2. Herceptin is a humanized monoclonal antibody (known as trastuzumab) that was approved by the FDA in 1998 for breast cancer treatment and was the first genomic-research-based targeted anticancer therapeutic entered into clinical practice [77]. Its effects are achieved through the binding in the HER2 receptor (also known as Neu or ErbB2), a member of the epidermal growth factor receptor (EGFR; also known as ErbB) family of tyrosine kinases, and its prescription is based on the expression level of HER2 in the patient's tumor tissue (individualized therapy) [88]. The recent elucidation of the crystal structure of the entire extracellular regions of HER2 complexed with the Herceptin antigen-binding fragment (Fas) gives new information on the drug-receptor structural interactions, and this knowledge may lead to better drug design and development of new therapeutics of this type [89]. Furthermore, such studies envisage a better understanding of cancer biology at the molecular level and permit the design of more specific pharmacogenomics studies to help establish pharmacotyping in cancer chemotherapy. In particular, such an interesting step related to human breast cancer progression and metastasis is considered in the recently published work on the gene expression profiles of the premalignant, pre-invasive, and invasive stages of this type of tumor, as well as the identification of a "gene signature" for breast cancer metastasis to lungs [90, 91]. Through this approach of genomic analysis, the better understanding of disease pathogenesis and metastatic potential can be achieved and the identification of specific genomic targets for better drug development could

also be attained. Moreover, by analyzing gene expression profiles in cancer pharmacotherapy treatments, it would be possible to characterize molecular gene networks that in turn might have important clinical cosequences for improving patient care. This happened in the case of ALL where 124 genes were identified to discriminate between different treatments of chemotherapeutic agents (methotrexate and mercaptopurine), a result that can be reversely applied afterward in order for the individualized therapy to be based on the expression level of such genes. Such a direction implies the application of genomic analysis of the identified genes for each ALL patient before initiating therapy with the referred drugs [92]. This procedure that uses transcriptional profiling analysis has been recently proposed as one way for applying pharmacogenomics in cancer pharmacotherapy [93]. Overall, however, the accumulated knowledge at the molecular level is expected to help toward elucidating the underlined complexity of both cancer biology and anticancer drug response variability. In any case, however enriching our knowledge of the molecular biology of cancer will ensure that better pharmacological interventions will be achieved in the near future.

2.6 THE CHALLENGES IN PHARMACEUTICAL AND MEDICAL EDUCATION TO MEET THE CENTRAL DOGMA OF PHARMACOTYPING AS WELL AS OF PERSONALIZED AND INFORMATION-BASED MEDICINE

The achievements and challenges in pharmaceutical research that have already been discussed in previous sections have added new and innovative knowledge in basic pharmacology and therapeutics and now stress for the appropriate adjustments in education and curricula in both medicine and pharmacy faculties [94–96]. Also, new roles for healthcare providers have emerged in the changing environment of pharmacotherapy and clinical practice that clearly coincide with their need for better education in pharmacogenomics and personalized medicine. It is evident that better training will be achieved by the development of new curricula based on the integration of drug-related genomic knowledge and bioinformatics technologies into the teaching process. However, healthcare educators already face difficulties in teaching pharmacogenomics and personalized medicine concepts in order to give students the skills and the knowledge to keep them up to date with recent advances in relevant drug-related issues [94]. The classic background bridge of physiology with chemistry and pharmacology needed in order for students to understand drug-related actions and effects in the body has now been expanded to include the knowledge coming from biochemistry, molecular biology, genetics, and finally genomics (Figure 2-2). The latter is now considered crucial for more thorough understanding of several aspects of drug delivery in order for future health and pharmaceutical care practitioners to improve their skills for better drug selection, dosage regimens, and co-administration of drugs in individual patients. Undoubtedly, this need for better training in pharmacogenomics, for both educators and healthcare providers, will be in increasing demands in the years to come, because developments are achieved by genomic technologies in all drug-related areas and rapidly introduced into health care and clinical practice [5, 10, 25, 94]. However, the successful integration of such knowledge in the educational process

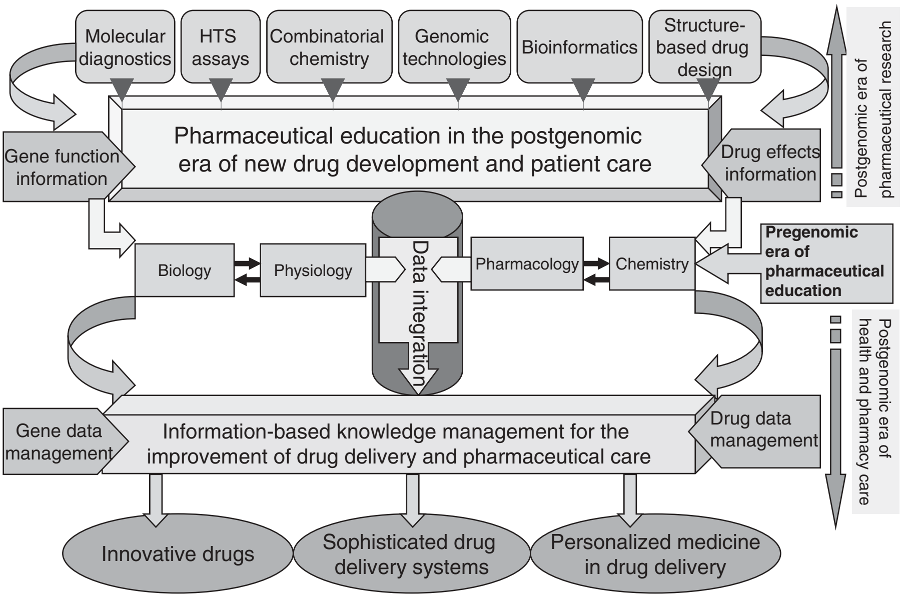

Figure 2-2. Convergence of genomic and clinical knowledge in postgenomic new drug development and health care (see the text for details).

is a difficult task. At first, this means the development and use of new interactive computer-assisted learning methods capable of combining drug-related information with the function of genes and proteins being expanded through the genome and proteome. Second, it implies that the proper introduction of these programs into the teaching process organized in a tight timetable for completing both theory and clinical practice is needed [25, 97–100]. Another challenging issue in the design of new curricula has to deal with students' future demands to keep pace with the new trends in clinical and pharmacy practice rapidly entering and enriching the drug-related era, even after their graduation, because such profound changes in pharmacotherapy are continuously entering into the clinics, thus affecting the practice of modern medicine and pharmacy.

Pharmaceutical education also has to address some ethical aspects related to the application of genomic technologies in pharmacotherapy. In other words, by integrating genomics data into the clinical practice and the drug delivery process, several societal- and clinical-related issues are raised and must be taken into account during the educational process. It is evident that the application of pharmacotyping requires the health and pharmaceutical care practitioner to look into the patient's genetic makeup and to correlate the extracted information with clinical knowledge in standardized pharmacogenomics protocols in order to validate the compatibility of the drug dosage profile for the individual patient examined. In addition, pharmacogenomics data impinge on people's genetic variations and traits implicated in altered drug response that are usually different among populations from various parts of the world [15, 101, 102]. So, an obvious question is raised: How can pharmacogenomics-based molecular diagnostic tests be clinically tested and validated in order to be generally applied to all populations around the world,

by taking apart the patient's ethnic or racial origin? The same question seems to apply to the case of the drug developmental process and the criticism developed regarding the use of pharmacogenomics criteria for the stratification of patients recruited in clinical trials in order to gain better benefits for the efficacy and safety of the drug being tested [103–106]. As recently claimed, at least 29 drugs (or combination of drugs) have been shown to produce different effects in terms of efficacy and safety among ethnic or racial groups [102]. Although there is enough skepticism on these issues, one cannot easily preclude the discussion of such phenomena from the drug delivery process and must group patients according to the existed drug-related information that correlates with variability observed in pharmacological response. The latter is strengthened by the fact that several individuals show a genetic etiology implicated in their altered pharmacotherapy outcome. In any case, the categorization in pharmacotherapy profiling, i.e., pharmacotyping, must be focused and always be referred to specific drugs and not to specific ethnic populations [5, 25]. In addition, the development of DNA-based molecular diagnostics by no mean must dismiss the utilization of classic biochemical tests such as measurement of enzymatic activity, but they have to work in parallel. As molecular diagnosis is getting simpler, cheaper, and readily automated, then the application of pharmacogenomics will become more easily integrated into the clinical practice [107–110]. Undoubtedly, as the field of pharmacogenomics and personalized medicine continues to expand toward the development of relevant clinical research data, more issues will be raised for society that will need to be addressed. However, until pharmacogenomics research is generally accepted in patient care, its beneficial clinical impact together with the ethical and societal aspects raised must be taken into consideration by all scientists involved in its application to clinical practice. In particular, clinicians along with pharmacists and bioinformaticians must work together in order for pharmacogenomics clinical use to be compatible with good pharmaceutical and clinical practice guidelines [5, 25]. Furthermore, issues related either to quality or validation of the genetic tests that could be applied in pharmacotherapy and therapeutics must be clearly addressed, before the usage of genomic information in routine patient care. In any case, however, the positive consequences in the clinical practice will be greatly enhanced by imperatively incorporating the fundamental principles of pharmacogenomics, personalized medicine, and pharmacotyping into the core curricula of pharmacy and medical schools. And for sure, this will be beneficial for both health and pharmaceutical care, as well as for the society and the public in general.

2.7 THE DEVELOPMENT OF INFORMATION-BASED PLATFORMS TO ENSURE MAJOR BENEFITS FOR PHARMACOTYPING IN CLINICAL PRACTICE

As mentioned, genetic variations detected in genes encoding proteins implicated in drug action could affect their function and thus might result in an altered drug response (e.g., decreased metabolism, inadequate intracellular transport, impaired function on target site, etc.). Also, genomic technologies provide valuable techniques for uncovering the molecular mechanisms leading to pathogenesis and phenotype of specific human diseases. The accumulated data are organized into specific

databases; most of them can be accessed through the Web. Some of these functional genomics databases related to genetic disorders, gene polymorphisms, ADRs, and drug response variability are shown in Box 2.3. In this frame of genetic research, new genes, proteins, and genetic variations of clinical importance can be detected in individuals, because the new technology allows the screening of thou-

sands of genes simultaneously. Genotyping and haplotyping analysis of individuals can identify specific gene variations and correlate them with drug effects, an approach that can obviously lead to individualized drug therapy. Furthermore, the conventional concept applied in drug therapy of considering patients suffering from the same disease as the homogenous population and using a similar drug therapy of all patients is changing in the genomic era. Under the new bioinformatic and genomic technologies used in personalized medicine, each patient is being handled as an individual, a practice that applies differentiation in pharmacotherapy [5, 25]. As a matter of fact, the detection of SNPs or other variations and the establishment of specific genotypes and haplotypes for several genes could explain why one patient responds well in drug therapy, another does not, or even why some people experience serious ADRs. Overall, if our understanding of these idiosyncratic pharmacological effects is finally achieved, then drug prescription would be greatly influenced. In fact, this will be a major transition in pharmacotherapy because pharmacotyping will be finally achieved, meaning that the physician could be based on the patient's genotyping–haplotyping analysis data for initiating and maintaining drug dosage therapeutic regimens for individual patients [5, 10, 25]. As the future prescription process is expected to be done by the physician in a fully

computerized environment with the aid of genomic and bioinformatic information concerning patient status, pharmacotyping could better ensure drug efficacy and safety. Such a case also means a transition from a drug-selection process mainly based on the physician's own experience into a more, highly integrated, information and computer-aided pharmacotherapy, thus making drug delivery digitized, more efficient, and safer. It is evident, however, that the genetic information derived from pharmacogenomics studies must be incorporated into clinical practice in such a way to assess simultaneously, besides drug efficacy, the risk of ADRs attributed to specific drug specimens. This fact can be further exploited through the recent scientific achievements of nanotechology and nanomedicine that obviously facilitate the development, validation, and establishment of information-based infrastructure in health care. As the advances in health sciences, either at a basic or a clinical level, are incorporated into clinical practice, nanotechnology can create the suitable diagnostic and drug delivery platforms in the healthcare system for better exploitation of such information at the molecular level. However, the path toward this goal is difficult enough, especially considering the existing complexity in physiology of individual cells and even more in the whole organism. The latter coincides with the high-level degree of cellular dynamics and homeostatic capability to respond to intrinsic or environmental factors by extremely complex structural and functional diversity. Toward this direction, the successful development of suitable nanodevices and the construction of biocompatible nanomaterials in nanomedicine implies that several factors ranging from the level of physiology and molecular biology to that of physics and chemistry must be taken into consideration. Furthermore, the identification of functional SNPs and the establishment of specific haplotypes for genes implicated in drug response, or ADRs, could also be used as a marker for drug prediction effects in a given individual, or even for a specific group of patients [25]. In this way, a standard framework for information-based medicine must first be developed, in order for this later approach to support an infrastructure for personalized medicine to achieve pharmacotyping in routine pharmaceutical care.

Another crucial aspect toward the successful application of pharmacogenomics and personalized medicine is related to the way in which the unprecedented load of the genomic information available at the molecular level has to be easily and rapidly transformed into a type-form applicable for everyday use by the medical practitioner or other specialties in health care. Indeed, the fast growing accumulation of genomic data concerning drug action is a real challenge that needs to be clarified in terms of the development of suitable tools capable of analyzing such information in a manner to be readily compatible for clinical use. This is of great importance in current drug delivery and biomedicine. In such a case, the validation of the genomic data mining processes will totally be based on the development of suitable computerized and data integration systems in order for these then to support the clinical transformation of the gathered genotyping and haplotyping profiling data from individual patients, before making such information applicable for routine patient care. Moving toward personalized medicine also means the existence of tools and molecular diagnostics capable of assessing genome-related clinical information in laboratory medicine to make the extracted information easily applicable by the physician. This is task very difficult, because before the transfer of techniques from genomic-related research laboratories to those used for the routine analysis of clini-

cal samples in diagnostic laboratories, these techniques must be extensively assessed for their ethical, social, and cost–benefit consequences [104]. As a consequence, the gradual integration of technologies transferring genomic information into the clinic needs the development of carefully selected and evaluated specific genetic biomarkers for the diagnosis of disease and prediction of drug response, as well as the use and application of genome-wide linkage analysis capable of genotyping, gene array, proteomics, transcriptomics, and metabolomics profiling [5, 105–107]. These developments of laboratory medicine should also highlight the way that must be undertaken in order to assure the level of quality and validity needed in genetic and molecular diagnostics tests. If this is confirmed in practice, then the individualized drug delivery profiling based on a patient's clinical, genomic, and bioinformatics data will be achieved in pharmacotherapy, e.g., pharmacotyping [5, 10]. Furthermore, the advent of specialized techniques coming from the advances of functional genomics will greatly influence the application of genomic information in laboratory and clinical practice. This also means that unified platforms must be developed to permit compatibility in handling different data gathered from unrelated sources like those of drug databases, clinical trials, DNA sequencing, and functional genomic analysis, in a way to ultimately support the clinical application of pharmacogenomics, personalized medicine, and pharmacotyping in health care.

The use of computational and bioinformatics approaches to predict the pharmacokinetics (absortion, distribution, metabolism, excretion; ADME) and pharmacodynamics properties of a drug are well appreciated throughout the process of drug development and delivery. Moving forward, the application of *in silico* methods and technology to evaluate safety and efficacy issues in pharmacotherapy by predicting mainly the emergence of drug interactions and ADRs in clinical practice are now considered major advancements to ultimately improve the success of new drug discovery and delivery outcomes [111]. Unfortunately, the data and the information generated up to now through the application of genomic and high-throughput technologies are impressive in scale but limited in clinical usefulness due to different database system formats and organization. For such an effort to finally succeed, information-based platforms in the drug development era and health care have to be developed to evaluate and integrate knowledge from different genomic and clinical sources in a manner that is simple for the end user. To this end, the application of semantic technologies with ontologies able to integrate the proper knowledge in a way that will be reusable by several applications and in different scientific areas can be a more beneficial approach toward better and quicker exploitation of genomic information in health care and therapeutics [112]. In any case, however, a crucial aspect in health care and pharmacotherapy to achieve major benefits from the technological and scientific advances in genomics and bioinformatics has been to create infrastructure and utilities that easily integrate each time the knowledge generated from different disciplines and facilities.

The clinical integration of genomic data in information-based platforms will also be greatly advanced by careful design and experimentation of pharmacogenomic studies, by ensuring genetic test quality, and evaluating and validating the data in routine patient care. This direction in medical and pharmacy practice will positively affect the rate by which genotyping data are transformed into specialized types applicable in personalized medicine, thus allowing pharmacotyping concepts to be

generally accepted as the new dimension in drug delivery to ensure drug efficacy and safety. The future advancement of patient care is directly related to the ability of medical practitioners to collaborate with other specialties to apply genomic technologies in clinical practice through the development of suitable tools and information-based platforms compliant with the good pharmaceutical and clinical practice guidelines [5]. Although this direction needs a multidisciplinary approach in order to finally be achieved, a recently published study has clearly shown that it is an affordable task. In particular, the maintenance warfarin dose was estimated through an algorithm generated by evaluating at the same time several clinical, pharmacogenetic, and demographic factors that were obtained before the warfarin initiation therapy was applied to patients [113]. The development of such a pharmacogenomics-based algorithm to predict an individual's response to coumarin therapy and the patient's maintenance dose has been recently discussed, showing that the better elucidation of genetic variants that can affect the coumarin drug response is an efficient and beneficial way to improve pharmacotherapy outcomes [114]. However, before the generalized application of such pharmacotyping/pharmacogenomics concepts in drug delivery, the complexity of personalized prescribing in terms of raised ethnicity issues has clearly to be addressed and dismissed in clinical practice [115]. By means of suitable, cost-affordable, and precious pharmacogenomics methodology, the *in vivo* selection, structural genomics analysis, functional verification, and clinical validation of biological samples can be safely performed in laboratory medicine in a manner that is compatible with information-based platforms. Overall, pharmacogenomics- and informatics-based approaches are expected to be finally used, giving hope, in the years to come, that the association of specific genetic markers with drug delivery dosage regimens, even for the therapy of complex diseases, is a realistic approach and can be achieved in everyday health care.

2.8 CONCLUDING REMARKS

By knowing how to better use drugs in clinical practice with enhanced efficacy and safety through the exploitation of genomic knowledge, the drug delivery era will certainly be advanced and medical practitioners will gain further roles in this challenging health and pharmaceutical care environment. But in order for this attempt to finally succeed, the appropriate education must be given to healthcare professionals through the development of new curricula and educational approaches. The training has to be focused on pharmacogenomics, personalized medicine, and pharmacotyping concepts as well as on bioinformatics and information-based medical practice. Also, the differences and peculiarities in health care and education found among several countries all over the world must be seriously taken into account, when the profound changes in post-genomic drug delivery and clinical practice are organized through the development of information-based platforms to implement and improve patient care. The trends in patient care-related issues or even the changes happening in one part of the world must be carefully examined and then adjusted before their use in other regions and vice versa. And for sure, this will be beneficial for both health and pharmaceutical care, as well as for the society and the public in general.

3.1.1 INTRODUCTION

Toxicogenomics is a relatively new discipline within the field of toxicology. The phrase was first coined in 1998 at the first Toxicogenomics Workshop held as part of the U.S. and European Community Consortium on Molecular Toxicology in Palo Alto, California. In its broadest sense, it is defined as the use of OMICS technologies to investigate issues of toxicity [1]. In its narrowest sense, it is defined as investigating the safety of compounds by using only cutting-edge gene expression technologies [2, 3]. In this chapter, the broader definition will be applied. Toxicogenomics is the use of OMICS technologies to assess the safety of new chemical entities or other compounds used in diagnostics or therapeutics [4–6].

OMICS technologies encompass genomics, proteomics, metabonomics, and pharmacogenomics [5]. Other descriptive terms (for example, transcriptomics, toxicoproteomics, and toxicogenetics) have been used intermittently, but most

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

references have centered on those listed above. Genomics is the study of gene expression through the use of high-throughput screening techniques, such as gene expression microarrays. Other gene expression techniques have been added to this category, and these methods include gene reporter assays, branched DNA amplification assay, scintillation proximity assay (SPA), rapid analysis of gene expression (RAGE), serial analysis of gene expression (SAGE), and various polymerase chain reaction PCR-based assays (e.g., real-time, quantitative, representational difference analysis, differential display) as has already been reviewed [7]. However, in some cases, it may be a stretch to qualify the method as "high-throughput" because several of these technologies either address gene expression more indirectly, such as SAGE, or can only address a few genes at a time, such as PCR. Proteomics, on the other hand, is the study of protein expression using either two-dimensional polyacrylamide gel electrophoresis (2DE) annotated by mass spectrometry (MS) or protein expression microarrays [7, 8]. Metabonomics is the use of high-resolution combinations of nuclear magnetic resonance (NMR), chromatography, or mass spectroscopy to evaluate metabolite profiles of body fluids or cells [9]. Finally, pharmacogenomics is the study of genetic variability to explain the adverse effects caused by compound–cell interactions [10–12]. Most pharmacogenomics studies have focused on single nucleotide polymorphisms (SNPs). This chapter will describe all of these OMICS methods and show how they can be applied to studying toxicity in pharmaceutical development. Case studies will be presented from very early citations to examples of current applications. Data analysis methods will not be discussed but are discussed in Chapter 2. This chapter will conclude with the authors' views on what the future may hold.

3.1.2 GENOMICS IN TOXICOLOGY

The applications of genomics to toxicology will be discussed with the focus on gene expression microarrays and how they have been used to investigate toxicity. Microarrays are covered in detail in Chapter 5.6. Briefly, they are manufactured by attaching pieces of DNA or RNA molecules to a nitrocellulose filter, a glass slide, or a silicon wafer [13]. Although early forms of arrays used nitrocellulose filters (now referred to as "macroarrays"), the most common substrate used today is a glass slide. Once the arrays have been printed with portion(s) of DNA or RNA (referred to as "probes"), they can be stored for further processing. The next step is to make the "targets" or isolated RNAs from both control cells and treated cells. These RNAs are labeled with a tag (most commonly fluorescent) and hybridized to complementary probes on the printed arrays. The microarrays are washed, scanned, and image analyzed to derive quantitative values for each probe signal. The remaining steps include data analysis of this raw information yielding (1) statistical analysis of replicate arrays and a measure of the variability in the processing steps, (2) similarities between gene expression patterns of control and treated samples, (3) identification of significantly expressed genes that may be biomarkers, and (4) patterns of gene–gene and gene–cell interactions.

Microarrays have been used as a screening tool in drug discovery and development. However, the focus and application of arrays in toxicology differs from dis-

covery in several aspects. The emphasis in discovery is feasibility: to ascertain the interaction of the compound and drug target rapidly. The emphasis in toxicology is development and validation: to understand this interaction more fully and, more importantly, to assess if any adverse effects are occurring. The focus here is on (1) validation of the compound–target interaction, (2) the prediction of adverse effects, and (3) the discovery of any alternative mechanisms of action resulting in "off-target" effects and aiding in the redesign of the candidate to a less toxic substance.

One of the most significant factors in microarray experiments is the experimental design. The overall design is dictated by whether a one-color (one label) or two-color (two labels) array system is being used [14, 15]. A one-color system requires that the control and treated samples are run on separate arrays, and therefore, intra-array as well as interarray variability needs to be considered. A two-color system requires that both the control target and the treated target compete for a complementary probe molecule on the same array. In this system, the importance of the intra-array variability is lessened. This aspect is the same whether a discovery approach or a toxicology approach is being used.

However, several aspects of the experimental design do differ between microarray screens used in discovery or toxicology. In toxicity assessments using microarrays, the emphasis on validation is an essential requirement of the experimental design. Particular attention needs to be paid to (1) types of species; (2) gender; (3) cell or tissue system; (4) treatment scheduling, dose, and route; (5) appropriate controls; (6) numbers of replicates, and (7) correlation with independent morphological and pathological toxicity assays [4, 5, 14]. Making these choices is critical for minimizing the process variability in order to maximize and visualize the biological variability. In 2001, The Microarray Gene Expression Data (MGED) Society proposed a list of guidelines for microarray work, known as the Minimum Information About a Microarray Experiment (MIAME) guidelines [16]. These guidelines are recommended requirements for how experiments are designed and reported. A set of guidelines specifically for toxicogenomics applications was drafted, but this draft has not yet been agreed to [17, 18].

Another aspect unique to toxicology research is the emphasis on analyzing the activity of annotated genes as opposed to unannotated genes. Annotated genes are genes whose sequence and function is already known. Unannotated genes are genes whose sequence is known but have not been assigned a function. As the focus for toxicology is validation, one priority is correlating significant expression of annotated genes observed in the data with their previously published values. A secondary priority is discovering which annotated genes or proteins are involved in any adverse or "off-target" effects. The final priority is discovering whether any unannotated genes are involved in these adverse effects and what their function or role may be. Therefore, when selecting microarrays to use, arrays that have the most annotated genes are preferred. Two exceptions to this recommendation are (1) whole genome arrays and (2) focus arrays. The availability of whole genome arrays, or arrays containing the entire complement of genes for that organism, make the selection of arrays biased toward annnotated genes a mute point. Focus arrays are sets of a smaller number of genes printed several times on one substrate. These arrays allow for profiling different samples using one array and, conceivably, hundreds of compounds could be screened in a high-throughput manner.

A third aspect of the experimental design that differs is the use of control or untreated samples. Discovery-focused experiments have emphasized the use of pooled samples to maximize consistency and minimize cost [19–25]. Pooled samples are individual samples from a cell or tissue system within a species and from the same treatment group that are pooled together to make one sample. In some cases, the control samples (from normal, non-diseased individuals) are pooled to make a "universal" reference [19]. However, the concerns are that (1) the resulting gene expression is an average of the group of samples, (2) the whole range of expression for the individuals within the group is not observed, and (3) pooling can only take place if the biological variation is greater than the process variation. [21–24]. One proposed method to address some of these concerns is "sub-pooling" where only subsets of samples are pooled and there are still replicates run for each group [25].

Toxicology-focused experiments may also include different sets of control samples. One set of control samples includes untreated samples both at the initial time point as well as at subsequent time points. If sufficient activity is found in the untreated control curve, this activity may need to be subtracted from the activity of the test curve. Another set of control samples includes samples from treatments using both positive and negative control compounds. Investigating the gene expression of the test compound is done by comparing it with the gene expression of the known control compounds. All of these controls need to be woven into the data analysis scheme.

As the focus is on validation, part of the evaluation is to determine how much the individual samples from a group vary in their gene expression. If the samples are pooled, the differences between responders and nonresponders will not be seen [24].

To understand toxicogenomics, it may be important to understand how microarrays evolved. An ongoing effort for developing more efficient sequencing by hybridization methods led to various initial microarray efforts where large numbers of genes could be screened at a time [26–30]. The first use of a microarray was in 1987 by Augenlicht et al., where macroarrays were used to differentiate a disease state [31]. In this case, cDNAs from a reference polyA mRNA library of the human colon carcinoma cell line, HT-29, were inserted into bacterial plasmids. Over 4000 clones were isolated and gridded onto several nitrocellulose filters. Radiolabeled cDNA probes from several biopsy samples (ranging from patients at low risk for colon cancer to familial adenomatous polyposis [FAP] patients to colon cancer patients) were then hybridized to the filters. The amount of radiolabel was scanned and analyzed. The amazing fact from this experiment was that a high percentage (20%) of FAP biopsies (in which the cells had not yet accumulated into adenomas) was upregulated as compared with the low-risk biopsies. These results suggested that increased gene expression seemed to correlate with early stages of the disease.

Initial toxicology studies using microarrays focused on screening and prioritizing lead compounds. Gray et al. designed a combinatorial library of protein kinase inhibitors used in cancer therapy and initially screened the compounds through an *in vitro* toxicity activity assay [32]. Then, three compounds were selected, and their interactions with yeast were investigated with oligonucleotide microarrays. The microarray results confirmed the diminished activity of one compound observed

in the *in vitro* assay. Another collaborative study between Incyte and Tularik screened several lead compounds for efficacy and toxicity using two-color microarrays [33]. The result was that the optimized lead compound had a similar profile to a known toxin, which led it to be redesigned to a better nontoxic lead compound.

One early study focused on discovering alternative modes of action. Karpf et al. used microarrays to broadly screen for genes expressed when a colon adenocarcinoma cell line was exposed to 5-aza-2′-deoxycytidine [34]. Several genes were significantly expressed. When investigated further, an alternative pathway was discovered and linked to the signal transducer and activator of transcription (STAT) genes.

The first comprehensive gene expression profiling time-course study using microarrays was first cited in 1998 by Cunningham et al. [35–38]. Using an acute short-term exposure regimen, rats were treated with toxic doses of three known hepatotoxins: benzo(a)pyrene (BP), acetaminophen (APAP), and clofibrate (CLO). mRNA isolated from the livers were analyzed using a cDNA microarray containing 7400 rat genes. Significant gene activity was observed at the early time points (12 hours, 1 day, and 3 days), and less activity was observed at the later time points (7, 14, and 28 days). All three compounds resulted in different expression profiles. Several cytochrome P450 genes and genes involved in phase II reactions were expressed over all six time points; however, the genes were induced at different times depending on the compound used (Figure 3.1-1). Three different data analysis methods were compared. It was hypothesized that both nongenotoxic (causing damage by a non-DNA mechanism) APAP and CLO would have the most significantly expressed genes in common compared with genotoxic (damage caused by a DNA mechanism) BP. However, with all three analysis methods, APAP and BP showed the most overlap of significantly expressed genes. Interestingly, both APAP and BP have their primary metabolic pathway involving cytochrome P450, whereas the metabolism of CLO involves both cytochrome P450 and β-oxidation.

APAP 0hr	APAP 12hr	APAP 24hr	APAP 3d	APAP 7d	APAP 14d	APAP 28d	BP 0hr	BP 12hr	BP 24hr	BP 3d	BP7d	BP 14d	BP 28d	CLO 0hr	CLO 12hr	CLO 24hr	CLO 3d	CLO 7d	CLO 28d	Gene

Figure 3.1-1. Normalized differential expression values for each gene across all time points (0 h, 12 h, 24 h, day 3, day 7, day 14, and day 28) for the following treatments: acetaminophen (APAP), benzo(a)pyrene (BP), and clofibrate (CLO). The highest relative expression is 1.0, and the lowest is 0.1. Three genes from the cytochrome P450 family (CYP1A2, CYP2B1, and CYP4A3) and two genes from the glutathione-S-transferase family (GST-α and GST-θ) give expression profiles that are similar to other members of the family but not identical. Gene expression profiles differ among all three gene families: CYP, GST, and sulfotransferase (ST).

Since these early citations, the use of gene expression microarrays as a tool for predictive toxicology has progressed. An early emphasis was to use microarrays to classify compounds based on their resulting gene expression profiles [39–46]. More recently, specific "sets of genes" giving rise to a gene expression profile have been used to distinguish classes of compounds [47, 48]. For example, Hu et al. showed through hierarchical clustering that distinct differences were observed between the gene expression profiles of direct- and indirect-acting genotoxins. When an array of over 9900 probes was used, a set of 58 genes could distinguish between these classes of compounds.

Another emphasis was to use gene expression microarrays to investigate mixtures. The profiles of the cellular interactions of mixtures were compared to the profiles of each component of the mixtures [49, 50]. Nadadur et al. compared the profile of residual oil fly ash (ROFA) in rat lung to the single profiles of vanadium sulfate and nickel sulfate, which are known components of ROFA. ROFA is derived from the exhaust plume of a power plant and is used as a model mixture to investigate the effects of air pollution. Using a focus macroarray, 12 genes were found to be significantly expressed in all three treatments. In a more recent study, arrays were shown to be able to distinguish toxic components of another type of mixture, wastewater effluent. From this study, Wang et al. found 11 genes that may ascertain the presence of endocrine-disrupting compounds in the environment [51].

A third emphasis was to match gene expression profiles to phenotypic changes. This correlation is the current goal for toxicogenomics. It will help toxicogenomics to be established as a tool in the regulatory arena. Early investigations focused on correlating gene expression from *in vivo* biological systems to gene expression from *in vitro* systems [52, 53]. Taking this concept further, attempts were made to correlate gene expression with specific organ regions exhibiting toxicity [54]. More recent studies have focused on anchoring specific cellular histopathological changes to gene expression [55–61]. To identify these changes, investigators have used laser capture microdissection (LCM) to extract specific cells exhibiting the phenotypic changes and then comparing the gene expression profiles of these cell populations with "normal" cell populations [62–66].

Finally, the most pressing issue in toxicogenomics may be the relevance of gene expression to toxicity. In other words, how does both the qualitative and the quantitative expression of a gene relate to toxicity? Several studies, including most of the papers already cited, have attempted to find this answer. Investigations by Heinloth et al. and Zhou et al. reported seeing gene expression changes before the observance of the overt toxicity [63, 67]. In each paper, *subchronic* doses of a toxicant were used and links of their expression with phenotypic changes were attempted. Today, research is ongoing, with the ultimate goal, to define a set of biomarkers that can predict toxicity earlier than the occurrence of phenotypic changes.

3.1.3 PROTEOMICS IN TOXICOLOGY

Two new words, *proteome* and *proteomics*, were coined a decade after classic terms such as *genome* and *genomics*. Here *proteome*, the complement of a *genome*, refers to the expression of all proteins in an organism, organ, or cell line at any given

time. The study of the proteome, its interactions, and its post-translational modifications (such as glycosylation, phosphorylation, etc.) that may be associated with a specific disease or toxicant is defined as *proteomics* [68, 69]. One advantage of proteomics is the ability to profile several thousands of proteins on a single platform and provide insights into post-translational modifications. Another advantage is that because proteins govern the normal physiology and disease processes, a more accessible endpoint of any changes in gene expression can be determined by direct analysis of proteins. Also, unlike genomics, proteomics offers the advantage of readily assaying both tissues and body fluids (e.g., plasma and serum) to investigate the molecules correlating with disease and drug action [70]. The proteomic analysis of body fluids is of particular interest as it can provide a noninvasive method for biomarker identification [71].

In the realm of toxicology, proteomics is one of many new technologies being used today to identify novel protein biomarkers and signature patterns in protein profiles that measure sensitive cellular changes in response to xenobiotic exposure [72–75]. The most widely used technique to date for proteomic science is high-resolution 2DE coupled with MS. First developed in 1975, it separates proteins in the first dimension based on their isoelectric points and in the second dimension by molecular weight [76]. Typically, 2DE can resolve hundreds to thousands of proteins from a single sample [77, 78]. To avoid overcrowding on a single gel, researchers now run multiple "zoom" gels that cover narrow pH ranges (e.g., covering 1 pH unit) [79]. In the mid-1990s, 2DE was coupled to MS allowing for annotation of the resolved spots. Proteins resolved using 2DE are analyzed by MS to give mass spectra. Subsequently, individual spots are excised from the gel and trypsin-digested to give shorter peptide fragments for sequencing. With the help of software programs and sequence databases, the peptide mass spectrum is compared with known partial gene and protein sequences and is then assigned an annotation. Recent developments in MS techniques, such as "tandem MS" (MS/MS), allow for better analysis of protein sequences, by avoiding ambiguity arising when MS data match more than one protein sequence. A more detailed description of proteomic methods is found in Chapter 14.2.

The use of proteomics in toxicology can be divided into two classes: (1) investigative studies and (2) screening/predictive toxicology [71]. The mechanism of toxic damage in several model systems has been elucidated with proteomics [72, 79, 80]. But proteomics offers the prospect of identifying new toxic mechanisms along with traditional toxicology methods [74, 79, 81]. Such insights may provide valuable information about specific effects caused by a specific group or class of compounds. In addition to supporting investigative studies, proteomics promises to provide insight into screening and predictive toxicology. The screening of new compounds for toxicity can be possible by following specific signatures of protein expression, thus identifying them as predictive biomarkers of toxicity [82]. The sensitive nature of proteomics offers the detection of toxic effects at low dosage levels, which escape conventional screening methods, such as histopathology and clinical chemistry [83]. In addition, proteomics provides a method for the early detection of potential toxicity and the opportunity of ranking compounds during drug development. A recent review lists publications that use proteomics in toxicology studies, with the most popular application being biomarker identification [84]. The issues surrounding the experimental design and the emphasis on development

and validation covered in the previous section for genomics applies to proteomics as well.

As an investigative tool, proteomics has been used to determine the failure of several drug candidates due to adverse drug reactions [72, 74]. In an early study, Anderson et al. developed a rodent liver proteomic toxicity database [85]. This database, containing profiles of effects of 43 compounds on liver, was among the first available for the detection, classification, and characterization of a wide range of hepatotoxins. The development of such a database has considerable implications for predictive toxicology. The potential hepatotoxicity of a new and unknown compound can be determined by comparing its effects on the proteome against known toxins from the database [74, 85].

New biomarker discovery from such studies can lead to early detection of deleterious effects. In a more recent study, researchers validated toxicological protein markers from an *in vivo* system (rat liver) as well as from an *in vitro* system (human HepG2 cell line) [86]. They reported a total of 11 protein markers with reactivity toward multiple toxic compounds and no reactivity toward nontoxic compounds. An important conclusion from this work is that cells in culture can be used as an *in vitro* toxicity testing system to assess hepatotoxicity. However, in the future, a much more extensive study may be required to identify a larger group of toxicology markers to detect more diverse types of toxic reactions.

Toward understanding the mechanistic action of toxicology using 2DE, Fountoulakis et al. showed the hepatotoxic effects of paracetamol (acetaminophen) overdose in human and rodent liver [74]. They found that the expression of 35 proteins was altered after treatment with paracetamol or its nontoxic regioisomer 3-acetamidophenol. Paracetamol selectively increases or decreases the phosphorylation state of proteins. This effect translates to a decrease in protein phosphatase activity [80]. The control of cellular functions of cells may be lost as a result of the dephosphorylation of certain regulatory proteins due to paracetamol overdose.

A dose- and time-dependent proteomics study with gentamicin confirmed the histopathological findings of renal toxicity at high doses and renal regeneration during the recovery phase [72]. Gentamicin, a known renal toxicant, represents a class of aminoglycosides. The effects of gentamicin treatment were observed after proteomic evaluation of rat kidney cortex samples. Examination of rat serum samples exposed to varying doses of gentamicin identified a protein being consistently overexpressed. Surprisingly, this particular protein marker was present both at the low treatment dose as well as at early time points before changes were observerd by routine clinical pathology. Intriguingly, during the recovery phase, the marker returned to control levels, thereby highlighting the sensitive nature of proteomics. Such protein markers are of great interest as they provide a noninvasive means of monitoring the onset of toxicity before any evident cellular damage.

Although 2DE offers a high-quality approach to proteomic research, it has certain limitations: Only major components of protein mixtures are visualized, the detection of low and high molecular mass of basic and hydrophobic proteins is inefficient, and it is a highly laborious technique. Alternative technologies, such as the protein microarrays, allows investigators to control conditions, such as pH, temperature, ionic strength, and different stages of protein modification, while monitoring the protein–protein interactions of thousands of proteins spotted on an array [87]. Protein microarrays not only provide a technique for high-throughput

screening but also a method to study interactions of proteins with non-proteinaceous molecules. Zhu et al. have developed a protein microarray of the yeast proteome from 5800 open reading frames [88]. The expressed proteins are purified and printed on glass slides with high spatial density to form a yeast proteome microarray. They were used to screen for interactions with proteins and phospholipids. The researchers identified many new calmodulin- and phospholipid-interacting proteins. Thus, protein microarrays can serve to screen for several hundreds to thousands of biochemical activities on a single chip. In toxicology, these arrays can be used to screen for adverse protein–drug interactions, to detect post-translational modifications leading to disease, and to identify biomarkers for drug targets and early disease detection [89].

A recent advancement is the coupling of MS with LCM for identification of tumor markers specific for cancer [89]. Specific cells of pathological interest are selected with LCM under direct microscopic visualization, laser captured, and removed from the tissues. The extracted lysate from the cells is applied directly to spots on the substrate of a surface-enhanced laser desorption/ionization (SELDI) MS, ionized, and desorbed from the surface, and a time-of-flight (ToF) proteomic profile of the entire cellular system is observed. This method has been recently applied to toxicology [90].

Several efforts are attempting to improve proteomic technologies to map and measure proteomes and subproteomes. However, no single proteomic platform seems to ideally suit and quantify the broad range of protein expression in a given cell/tissue system. More than one proteomic platform may likely be needed to distinguish the multiple forms and post-translational modifications of proteins, to address the inadequate annotation of proteomes, or to accomplish integration of proteomic data with genomic and metabonomic data. Additionally, advances in genomics data through investigations of pathways and subcellular structures induced by toxicity may guide studies in proteomics.

3.1.4 METABONOMICS IN TOXICOLOGY

The term metabonomics was derived from early work in Dr. Jeremy Nicholson's laboratory [9]. This term along with metabolomics has been used in several citations interchangeably [91–94]. Attempts have been made to clarify the definition of each term [95–99]. It seems that agreement has been reached where metabonomics is the broader encompassing term of metabolite profiling and metabolomics refers specifically to profiling in cells [9, 95, 98].

This technology is covered in detail in Chapter 14.3, but briefly it uses combinations of NMR, MS, and chromatography to profile multiple components in biofluids, tissues, or cells. The main advantage of metabonomics is the serial sampling of a biofluid noninvasively. The earliest papers used high-resolution ^{1}H-NMR alone for profiling [100, 101]. The technique became more sophisticated when bioinformatics tools, such as pattern recognition and expert systems, were applied to the data [102, 103]. Today, the following combinations of techniques are used: liquid chromatography–nuclear magnetic resonance (LC–NMR), magic angle spinning–nuclear magnetic resonance (MAS–NMR), gas chromatography–mass spectroscopy (GC–MS), LC–MS, capillary electrophoresis–mass spectroscopy (CE–MS), and

LC–NMR–MS [97, 98]. The first technique listed in the combinations above refers to the method used to separate the multiple components of the sample, and these components are identified using the second technique [96]. The advantages and limitations for each combination of techniques have already been reviewed [94, 97].

Two of the earliest papers using metabonomics in toxicology were studies by Nicholson et al., which investigated mercury and cadmium toxicity in the rat [101, 104]. Each of these papers used an experimental design that reiteratively sampled a biological system over either dose or time using high-resolution ^{1}H NMR. The changes in the urinary excretion patterns correlated with the expected histological changes. However, an interesting note was that in the case of cadmium, a urinary metabolite related to nephrotoxicity was found that was undetectable using traditional methods. A more extensive study that included a-naphthylisothiocyanate and 2-bromoethylamine showed changes in the metabolite profiles ahead of the time point where the clinical chemistry or microscopic changes would be detected [105].

As with the previously described OMICS technologies, one emphasis has been to profile groups of compounds using metabonomics [103, 105, 106]. Each compound gave a unique metabonomic profile and was successfully classified using pattern recognition techniques. A second emphasis was to be able to monitor not only biofluids, such as urine or plasma, but also tissues and cells. Moka et al. performed the first study to classify carcinoma biopsy samples by MAS–NMR [107]. Since then, two studies have used metabonomics to investigate toxicity using a wider approach where urine, plasma, and tissue samples are all analyzed [108, 109].

To collaborate and share information, a proposal for a users group in metabonomics was put forth [110]. Since then, the Consortium for Metabonomic Toxicology (COMET) was formed and the first report from this group was given in 2003 [111]. The final report was just published [112]. This report describes what methodologies have been assessed, the development of a curated database for metabonomic profiles, and computer-based experts systems for data analysis.

3.1.5 PHARMACOGENOMICS IN TOXICOLOGY

Pharmacogenomics and pharmacogenetics are two terms that have created confusion because they have been used interchangeably and defined differently by several authors [113]. The most widely accepted term, pharmacogenetics, is the study of an individual's response to a drug as determined by their genetic makeup [114]. Pharmacogenetics as a field of study has been around for several decades [113]. Early studies focused on observations of patient variability in metabolizing various drugs such as primaquine, succinylcholine, and dibucaine [115–118]. Comprehensive reviews have been written, including one by Werner Kalow, a pioneer in this field, and more details are covered in Chapter 5.7 [11, 113, 114, 119, 120]. In this chapter, the term "pharmacogenomics" will be used to refer to the use of high-throughput screening techniques for the detection of the genetic variation of an individual and its role in toxicity, especially in causing adverse effects.

In toxicology, most pharmacogenomics studies have focused on variations within the drug metabolizing enzymes (DMEs) [11]. These DMEs catalyze the phase I

and phase II metabolic reactions. Several examples have been cited for arylamine N-acetyltransferase (NAT1 and NAT2), thiopurine-S-methyltransferase (TPMT), glutathione-S-transferase (GST), as well as the various cytochrome P450 enzymes (e.g., CYP2A6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, and CYP3A4) [10, 11, 120–122]. Early studies showed that individuals with these genetic variations can be classified as "poor," "extensive," and "ultrarapid" metabolizers [114, 121, 123]. From a toxicity standpoint, this variability is extremely important in that poor metabolizers could accumulate the drug within their tissues causing a toxic response, whereas in extensive metabolizers, the drug has an extremely short half-life and may not stay around the tissues long enough to exert its desired effect. For example, an individual with the gene variant CYP2D6*2, which represents an "ultrarapid metabolizer," can possess a much higher activity for cytochrome P450 isozyme 2D6, whereas an individual with the gene variant CYP2D6*10 possesses a defective enzyme and therefore is a "poor metabolizer" [121, 123]. Individuals who have slow or fast metabolism rates have been observed in several mammalian species [124–128].

Early examples of polymorphisms being detected in a high-throughput manner are studies that used oligonucleotide microarrays containing perfect-match and mismatch sequences. These studies investigated polymorphic changes in breast cancer, HIV infection, and cystic fibrosis [129–131]. A more recent study used a chip containing over 11,000 SNPs to detect genetic variabilities in over 100 DNA samples—a high-throughput variation on association studies [132]. Another array format blended nanotechnology by using multiplexed nanoparticle probes with printed oligonucleotides to distinguish genetic polymorphic variants [133].

3.1.6 SYSTEMS BIOLOGY

Systems biology is a recent term that encompasses looking at the entire biological system from the molecular, cellular, tissue, organism, population, and finally, ecosystem levels. As Witkamp describes it, "systems biology is a realization that organisms do not consist of isolated subsets of genes, proteins and metabolites" [134]. It is also the application of network biology or comprehensive computational methods to analyze the data produced by the combination of OMICS technologies [134–137]. The ultimate goal of toxicogenomics is to predict compound–cell and cell–cell interactions *in silico*, and the application of systems biology brings this one step closer [5, 138, 139].

In attempts to obtain this goal, several studies have correlated datasets from combined genomics and proteomic studies and combined genomics and metabonomics studies. An early toxicogenomics study by Cunningham et al. combined the datasets from the rat toxicity study with three hepatotoxins evaluated by gene expression microarrays described earlier with a matched proteomics arm (Figure 3.1-2) [8, 35–38, 140, 141]. In this study, a portion of the gene and protein expression profiles matched but the remaining did not. Four other studies also tried correlating gene and protein expression in evaluating the effects of zinc, carbon tetrachloride, lithium, and bromobenzene [142–145]. The experimental design for these studies used only one or two time points with one dose, and in all three studies, only a portion of overlap between gene and protein expression was observed.

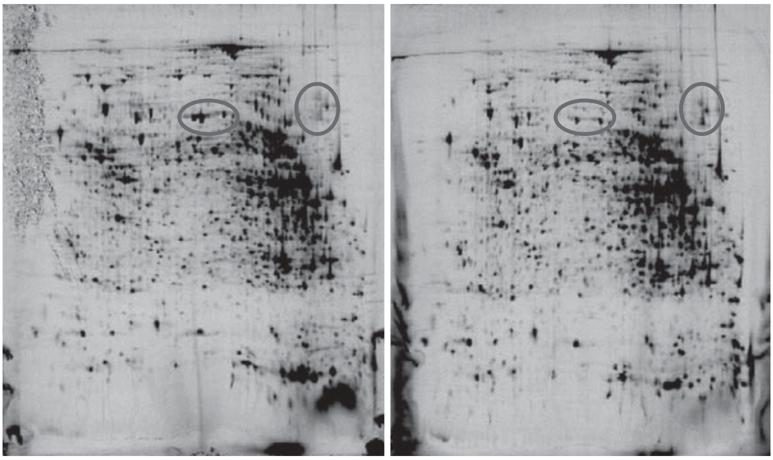

Figure 3.1-2. Proteome changes in livers at day 3 from rats treated with the vehicle DMSO (left) and clofibrate (right). The dose of clofibrate was a toxic dose at 250 mg/kg i.p. Two sets of specific changes are observed within the outlined areas.

Finally, Coen et al. attempted to correlate metabonomics with genomics [146]. They observed some overlap between the two technologies and, hence, concluded that these technologies are complementary in providing a view into toxicity.

A fully integrated approach using genomics, proteomics, and metabonomics was attempted by two groups of investigators. Schnackenberg et al. studied the hepatotoxicity effects of valproic acid [147]. Correlative changes in glucose metabolism were shown by both metabonomics and proteomics methods. However, no significant changes were observed with the gene expression method. Kleno et al. used genomics, proteomics, and metabonomics to investigate the hepatotoxicity of hydrazine [148]. Disruption in both glucose and lipid metabolism were present in all three datasets, and therefore, once again, these three technologies were shown to be complementary.

3.1.7 FUTURE TECHNOLOGIES IN TOXICOGENOMICS

The field of toxicogenomics continues to evolve and develop. For all the technologies listed above, research is continuing to develop more efficient, more high-throughput versions. The field of nanotechnology may aid in this effort. The various engineered nanomaterials may enable the current microarray format to be redeveloped on a nanoscale level and provide more rapid and possibly instaneous results. Some of these engineered nanomaterials, such as single-walled carbon nanotubes, are being developed for applications in the communications and information technologies field and may lead to increased capacity and advances in bioinformatics. The entire field of biosensors is being redeveloped on the nanoscale to nanosensors—from microelectronic membranes (MEMs) to nanoelectronic membranes (NEMs). A preliminary study done by Cunningham et al. assesses the toxicity of these nanomaterials using genomics (Figure 3.1-3) [5, 149, 150]. In this study, the gene expression

Figure 3.1-3. K-means clustering of gene expression profiles from human skin cells treated with TiO_2 (Compound A: A1, A2, A3), carbon black (Compound B: B1, B2, B3), and SiO_2 (Compound C: C1, C2, C3). Columns are the top 100 significantly expressed genes; rows are the samples representing triplicate arrays for each biological sample. The red color denotes upregulation of the gene, and the blue color denotes downregulation of the gene. Insignificantly-expressed genes are denoted by the black color. The expression profiles for TiO_2 and SiO_2 are more similar than the profile for carbon black. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

profiles of three known nanoscale materials were compared and two were found to be more similar with each other. This similarity correlated with the similarity in their chemical structures. As more and more engineered nanomaterials are being made, the applications for these materials in the life sciences will only grow. As a result, their safety will also need to be assessed.

In addition to the microarray formats discussed above, different substances are now being printed as reviewed by Cunningham [13]. Arrays are being manufactured with chemical ligands [151, 152], whole cells [153–155], tissue slices [156–158], peptide nucleic acids [159], and nanomaterials [160–166]. These new formats will increase the ability to investigate cell and tissue interactions more extensively than previously known.

Facing the future, other new technological fields are making their way to the forefront of research and could have pertinent applications for investigating toxicity. RNA interference (RNAi) is a burgeoning area (as covered in Chapter 7.6). This field was first thought to include only investigations of naturally-occurring microRNA (miRNA) molecules and synthesized short-interfering RNA (siRNA) molecules. An early paper used siRNAs to the aryl hydrocarbon receptor (AhR) and the AhR nuclear translocator (ARNT) to look at gene silencing [167]. Since this 2003 paper, many references have now reported using siRNA molecules as knockout molecules to investigate mechanisms of toxicity. miRNA molecules, on the other hand, have been sequenced and printed on macroarrays and microarrays [168–169]. These array tools may allow the expression of these molecules, and consequently, their function to be investigated. Recently, other types of short noncoding RNA molecules have been reported as well as naturally-occurring siRNAs [170–172]. It will be interesting to see what roles, if any, each of these new classes of short RNA molecules play in toxicity.

Another technological field is the exciting area of stem cells. Although work has been ongoing with adult stem cells for many years, research involving embryonic stem cells continues to hold great promise. Cell lines for mouse and rat have been

used in several research areas to develop new animal models and devise new therapies [173, 174]. The next front is human embryonic stem (HES) cells. Currently, this tool is in the midst of an ethics and morality debate [175]. However, the same debate was waged when fetal tissue was first used in the laboratory setting over two decades ago. If an investigator could direct the differentiation pathway of HES to more mature tissue-specific cells, the need for primary human tissue, which is already difficult to get, would be lessened. This application would increase dramatically the capability of *in vitro* toxicity assays.

Toxicogenomics is a growing and ever-changing field within toxicology. All of these advances in research and development could completely change the safety assessment landscape within just a few years. As the regulatory assays become more predictable, the time from discovery of a pharmaceutical agent to its market release will be lessened.

3.2.1 INTRODUCTION

The preclinical pharmacokinetics of protein pharmaceuticals is distinctively different from small-molecule drugs. The phase I and phase II metabolizing enzymes, for example, the cytochrome P450 and glucoronosyl transferases, which play dominant roles in the metabolism of small-molecule drugs, are not significantly involved in protein metabolism. Instead, because all protein pharmaceuticals invariably share a common polypeptide backbone, they are susceptible to proteolysis as a clearance mechanism. However, the disposition, pharmacokinetics,

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

and pharmacodynamics of proteins can be modulated by a variety of additional factors, including glycosylation and receptor binding, binding proteins, and neutralizing antibodies.

3.2.2 DISPOSITION OF MACROMOLECULES

3.2.2.1 Absorption

During drug development, the oral route is often targeted as a preferred route of administration for small molecules. However, the oral route is not usually an option for protein pharmaceuticals. Each organ in the gastrointestinal tract contains a variety of digestive proteases that enable it to break down nutritional proteins to small peptides and amino acids that can be absorbed in the intestine via secondarily active transport mechanisms. These digestive proteases also cause the extensive hydrolysis of the polypeptide bond in protein drugs in the gastrointestinal tract resulting in poor bioavailability. Protein pharmaceuticals are usually, therefore, administered via injection, such as the intravenous, subcutaneous, or intramuscular routes.

The absorption of protein drugs from extravascular sites is dependent on the size of the molecule. Upon subcutaneous administration, small molecules with molecular weights less than 1 kD predominantly enter the systemic circulation via blood capillaries, whereas subcutaneously administered proteins with molecular weights greater than 16 kD enter the systemic circulation predominantly via the lymphatic system. The extent of the lymphatic recovery after subcutaneous administration is a linear function of molecular weight (Figure 3.2-1) [1–5].

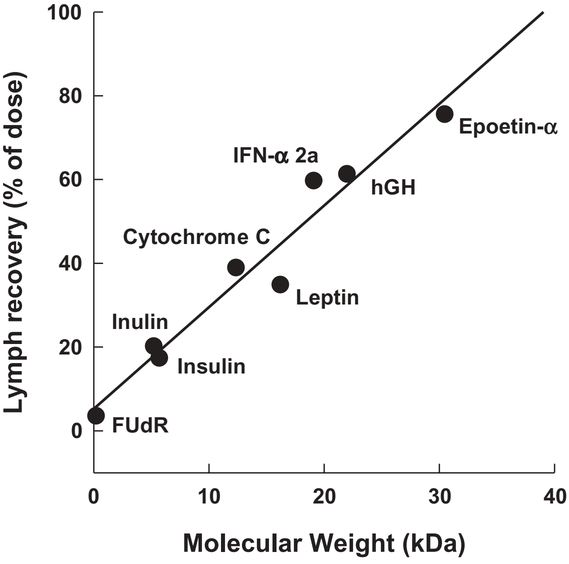

Figure 3.2-1. Linear relationship between cumulative lymphatic recovery and molecular weight of various therapeutic peptides and proteins. Data were extracted from the literature [1–5].

Nonparenteral routes of administration for protein drugs in general are not extensively used; however, recombinant human deoxyribonuclease I solution (dornase alfa or PULMOZYME) and, more recently, insulin powder by inhalation (EXUBERA) have been approved for clinical use in the United States [6]. The approval of inhaled insulin may provide the stimulus for greater interest in the inhalation route for other protein drugs in the near future. The lung presents a large surface area for transport and high permeability compared with other barriers. Inhaled insulin is administered as a novel powder formulation that is metered from a propellant-free metered dose inhaler. However, delivery to the lungs, particularly to the alveolar regions deep in the lung, presents several technological challenges and the overall system bioavailability (which is based on the amount of drug loaded into the inhaler device) of inhaled insulin is 9–22% that of the subcutaneous route. The reduced bioavailability is managed by dose adjustment and compared with subcutaneously administered regular insulin, the serum insulin concentrations after inhalation peak earlier (at 7–80 minutes compared with 42–274 minutes for subcutaneous regular insulin) and decay more rapidly; the pharmacodynamics of glucose changes are also correspondingly more rapid [7]. The duration of inhaled insulin action are comparable with regular insulin [6].

3.2.2.2 Distribution

The distribution of protein drugs is limited compared with that of small-molecule drugs and is primarily a function of the physico-chemical properties of the macromolecule and the physiological characteristics of the vasculature and cellular membranes [8]. Primary molecular descriptors, such as size, charge, and lipophilicity, will determine or influence the extent of specific and nonspecific protein binding and passage through various types of capillary endothelia [8]. The relatively large size of peptide and protein drugs alone can often account for the limited volume of distribution of these compounds, which is generally restricted to the extracellular space. Following intravenous injection, the initial volume of distribution for most macromolecules is confined approximately to plasma volume (3–8 L), and the total volume at steady state is typically only up to two fold greater.

Active transport and receptor-mediated uptake also may influence the biodistribution of macromolecules. For example, the internalization of monoclonal antibodies into cells may occur via Fcγ receptors, found on various immune and hematopoietic cells [9], or binding to membrane-localized antigens [10]. Thus, active uptake processes can serve to increase the volume of distribution to a large extent relative to that which would be expected based only on physico-chemical properties. Receptor-mediated endocytosis may represent a significant elimination pathway as well (see the Receptor-mediated elimination subsection) and is recognized as a major process influencing the overall disposition of macromolecules [11].

One must carefully interpret the volumes of distribution of peptides and proteins reported in the literature. Most studies rely on a so-called noncompartmental analysis to estimate primary pharmacokinetic parameters (see Section 3.2.3.1). However, this method is only valid for linear systems, assuming that the site of drug elimination is in rapid equilibrium with the sampling site (plasma). The former

condition is often assumed for compartmental models as well, including those with nonlinear mechanisms of elimination. Therefore, uptake processes and relatively slow or complex tissue catabolism may confound reported distribution volumes of select macromolecules estimated by these common methods.

Binding Proteins. For some therapeutic proteins, specific and nonspecific protein interactions can modulate distribution and activity. Soluble receptors are the best-characterized specific binding proteins and α_2 macroglobulin, an acute phase protein, has been implicated in the binding of several cytokines. Binding and neutralizing antibodies are another class of binding protein that will be discussed separately in the section on Immunogenicity, Binding, and Neutralizing Antibodies.

Soluble cytokine receptors (SR) occur naturally in human serum and urine and play a role in determining the disposition and biological activities of cytokines in health and in pathological states. Additionally, bioengineered soluble receptors and their immunoglobulin derivatives have been investigated as specific cytokine-inhibiting therapeutic agents [12, 13]. However, the physiological role(s) of naturally occurring SR is controversial and not well understood.

As expected, the SR can inhibit cytokine bioactivity by competing with the receptor and, when these antagonist-like effects are observed, the dose-response curve of the cytokine effect as a function of SR dose usually decreases monotonically, and almost complete inhibition is observed at the highest SR doses. In animal models, soluble receptors for interleukin-4 [14], interleukin-7 [15], interleukin-6 [15, 16], and tumor necrosis factor-α [17] have been shown to enhance rather than inhibit cytokine responses under certain conditions [17–19]. When these agonist-like effects are observed, the dose-response curve of the cytokine effect as a function of SR dose is bell-shaped, with no inhibition of cytokine bioactivity at low SR doses, maximal cytokine bioactivity at intermediate SR doses, followed by increasing inhibition of cytokine activity at higher SR doses. As the SR effects of the cytokines biological response is dependent on experimental conditions and can be either agonist-like or antagonist-like, the physiological roles of SR have been difficult to assess. Cytokines generally have short half-lives consistent with their physiological roles in cell-cell communication and the apparent SR-mediated agonism of cytokine activity occurs because the SR stabilizes the cytokine in vivo either by reducing the rate of spontaneous activity decay [17] or by increasing the half-life of cytokine [20]. The formation of SR-cytokine complex reduces cytokine-free concentrations, but the increases in circulation time can offset the effect of reduced receptor occupancy and contribute to overall increases in exposure [20]. The binding half-life of insulin-like growth factor-1 (IGF-1) in rats deficient in IGF-1 binding protein is 20–30 min; but in rats with normal levels of the binding protein, the half-life of IGF-1 increases 8–12-fold to 4 hours [21]. In the plasma, nearly 40% of human growth hormone (GH) is also bound to binding proteins; the high-affinity component of the GH binding activity consists of the extracellular domain of the GH receptor [22, 23]. The metabolic clearance of the SR-bound GH fraction is 10-fold slower than free GH because the bound GH is not filtered by the kidney and the competitive inhibition of receptor binding reduces elimination via receptor-mediated pathways [24]. Indirect evidence for the physiological role of SR binding is provided by the data from short-stature Mountain Ok people of Papua, New

Guinea who have SR levels 50% that of controls of normal stature; the levels of GH, IGF-1, and low-affinity GH-binding protein levels are comparable in the two groups [25].

Immunogenicity, Binding, and Neutralizing Antibodies. The bioactivity and distribution of therapeutically administered proteins can be modulated by their immunogenicity; humoral responses to therapeutic proteins can result in binding and neutralizing antibodies. Generally, chronic or intermittently administered proteins are more likely to be affected by these pathways than proteins administered for acute conditions. The underlying protein structure, aggregation state, and protein formulation can contribute to the risk of binding and neutralizing antibodies. Factors related to the dosing regimen such as dose, frequency, and route of administration are also important determinants. The role of disease-related and individual-specific variables to the development of antibodies is poorly understood. The time to development of antibody depends on the dosing regimen and immunogenicity of the preparation. For some proteins, the development of antibodies to endogenous proteins can cause serious adverse events (e.g., red cell aplastic anemia can occur with anti-erythropoeitin antibodies). The impact of antibodies on drug efficacy in clinical trials should be assessed during the period the antibodies are present.

As a case study, consider interferon-β, an endogenous cytokine, recombinant forms of which are used chronically in multiple sclerosis (MS). Two types of IFN-β exist: IFN-β-1a and IFN-β-1b. IFN-β-1a is glycosylated and has the same amino acid sequence as endogenous IFN-β. IFN-β-1b is not glycosylated, lacks the N-terminal methionine, and is engineered with cysteine replaced by serine. Two approved IFN-β-1a products exist that are dosed by the once-weekly, intramuscular, 30-μg and three-times-weekly, subcutaneous, 44-μg dosing regimens; the IFN-β-1b product is an every-other-day, subcutaneous, 250-μg dosing regimen. As with other protein drugs, some patients develop neutralizing antibodies (NAB) upon chronic administration of all IFN-β products. The proportion of patients developing NAB ranges from 25% for three-times-weekly, subcutaneous IFN-β-1a regimen to 2% for the once-weekly, IM IFN-β-1a regimen [26]. In a clinical trial where the weekly IM dose in the once-weekly, IM IFN-β-1a regimen was increased from 30 μg to 60 μg, the percentage of patients developing NAB titers greater than 20 after 3 years of treatment increased from 2.2% to 5.8% and suggests that, for a given route of administration, the frequency of IFN-β-1a administration is probably the major factor influencing the immunogenicity of an IFN-β product and the increase in dosage has relatively less impact. Published data from large randomized clinical trials demonstrate that disease activity in NAB-positive patients became similar to placebo-treated patients [27]. Interestingly, skin necrosis, an adverse effect that occurs with SC IFN-β administration, occurred only in the NAB-negative patients [27]. Despite the evidence from large clinical trials, some controversy exists regarding the appropriate clinical decisions for treatment of NAB-positive MS patients, especially those with a clinically stable disease, because (1) many NAB-positive patients test negative over the course of treatment [28], (2) no accepted IFN-β treatment biomarkers exist that are MS-relevant [29, 30] and, (3) market and competitive factors occur because of the availability of multiple IFN-β products for MS.

3.2.2.3 Metabolism

The cytochrome P450 enzymes, expressed in the endoplasmic reticulum of the liver, kidney, and intestine, are the predominant metabolizing pathways for small-molecule drugs. After the phase I oxidation reactions, small molecules typically are further modified by phase II conjugation reactions mediated by glucoronosyl transferases that render them hydrophilic for renal elimination. However, as noted earlier, the metabolism of protein drugs does not involve these small-molecule pathways: Endogenous pathways involved in protein homeostasis mediate protein drug metabolism.

As indicated earlier, proteolysis is the predominant mechanism for protein drug metabolism, but diverse endogenous proteolytic pathways exist in humans. Further, the half-lives of protein *in vivo* are, not surprisingly, regulated by a variety of intracellular mechanisms. The half-life of intracellular proteins is regulated via the ubiquitin pathway, which targets proteins to degradation in a large multimeric protease complex referred to as the proteasome. Ubiquitin is a widely expressed globular protein with a protruding carboxyl-terminus that tags proteins for degradation. Ubiquitin-activating enzymes activate through a process that requires ATP, and the activated ubiquitin is then transferred to a lysine on the target protein by another enzyme, the ubiquitin ligase. Multiple ubiquitin chains can be ligated on a single target protein lysine by conjugating glycine-lysine bonds between successive ubiquitin chains. Some target proteins are also tagged by binding proteins referred to as "recognin" that bind sequence elements called "degrons" that specify half-life. Sufficiently ubquitinated proteins are recognized and degraded in the proteasome. Although the ubiquitin pathway is critical for cellular protein homeostasis, its involvement in the metabolism of exogenously administered proteins is probably minor.

Some circulating proteins, most notably albumin and immunoglobulin G (IgG), have anomalously long half-lives because they are protected from degradation by specific mechanisms after cellular uptake. The best characterized of these protein-stabilizing mechanisms is the neonatal Fc receptor or FcRn, which is present on a variety of cell types and tissues including the kidney, liver, and lung endothelial cells, hepatocytes, monocytes, and intestinal macrophases. It confers a long half-life to IgG (mean half-life in humans = 23 days) relative to other types of immunoglobulins (half-lives for IgA, IgD, IgE, and IgM are 6, 3, 2.5, and 5 days, respectively). Most proteins generally undergo degradation in lysosome after pinocytosis and receptor-mediated endocytosis from the cell surface. However, the constant Fc region of immunoglobulin G and antibody-based drugs are internalized by pinocytosis or, when they bind, the cell surface antibody-binding Fcγ receptors. However, upon internalization into the endosomes, immunoglobulin G is bound by FcRn and the complex, upon endocytosis, is protected from proteolysis and recycled to the cell surface instead of being processed for degradation in lysosomes. The FcRn receptor for IgG is often referred to as the Brambell receptor after the authors [31] who postulated their existence to explain the relatively long half-life and the increased rates of IgG degradation at higher IgG concentration. Mice that are β_2 microglobulin-deficient do not express FcRn and have IgG half-lives that are 10–15-fold shorter than mice with intact FcRn [32–34].

Overall, 3 major mechanisms for clearing protein drugs exist: (1) renal, (2) hepatic, and (3) receptor-modulated.

3.2.2.4 Excretion

The rate of elimination of proteins is strongly dependent on the size, structure, and, in the case of chronically administered protein drugs, the presence or absence of antidrug antibodies. Renal clearance is relatively uncommon for protein drugs with molecular weights greater than 50 kD. Specific primary structural features such as the presence of a humanized immunoglobulin constant (Fc) region can confer prolonged stability via endogenous recycling pathways. Likewise, glycosylation and the addition of polyethylene glycol moieties (a synthetic modification often referred to as PEGylation) can also prolong circulation times.

Protein drugs with molecular weights less than 20 kD are filtered out of circulation in the Bowman's capsule of glomerulus of the kidney and enter the luminal space of the nephron. Even under pathological conditions, urinary excretion of intact protein is unusual. The filtered protein drugs are reabsorbed from the lumen and released into the circulation either as intact drugs or degraded into peptides. The proximal tubule is the predominant site for reabsorption, which transfers proteins into apical vacuoles that fuse with lysosomes. Lysosomal proteases degrade proteins into amino acids that re-enter the circulation. Small peptides can also be directly degraded by proteases on the luminal side of the renal tubule and the resulting amino acids can be reabsorbed by transport mechanisms.

Hepatic metabolism is important to the clearance of therapeutic proteins with molecular weights greater than 20 kD, although renal clearance can contribute to proteins as large as 50 kD. The Kupfer cell and hepatocytes of the liver are involved in clearing protein drugs.

Pegylation. Pegylation refers to the covalent modification of proteins by polyethylene glycol (PEG) moieties. As PEG is a hydrophilic, degradation-resistant polymer, pegylation can increase the circulating half-life of proteins, reduce renal elimination, alter the distribution, and reduce the immunogenicity of proteins [35]. The addition of PEG increases the molecular weight of the protein, which is instrumental in reducing renal filtration, and it provides a hydrophilic shield containing tightly associated water molecules that protects against proteolysis and some nonspecific interactions that mitigate therapeutic protein immunogenicity. However, pegylation can reduce receptor-binding affinity. When engineering pegylation during drug development, the effects of reduced receptor binding can be offset by the increased drug exposures; the improvements in circulating half-life and protein disposition effects and reduced immunogenicity benefit of this modification. The chemistry of PEG conjugation involves chemical activation of PEG followed by covalent attachment at the reactive amino groups of lysine or the N-terminal amino acid or the sulfhydryl groups of cysteine. As a rule of thumb, the molecular weight of the PEG moiety has to be comparable with that of the therapeutic protein for pegylation to be effective. Pegylation chemistry is also capable of conjugating branched PEG polymers that can increase the mass of PEG added at a each site and can better protect the protein therapeutic from degradation and immune recognition [36]. The pegylation approach is quite general and has

also been used for liposomes: It prolongs the circulation times of liposomes by reducing the rapid elimination by the reticuloendothelial system.

Interferon-α-2b (IFN-α-2b, PEGINTRON), which is used for treating hepatitis, is a case study on the impact possible with the pegylation approach because considerable preclinical and clinical data are also available for the IFN-α-2b unmodified by pegylation (INTRON-A). As a result of pegylation, the molecular weight of IFN-α-2b is increased from 19 kilodaltons to approximately 31 kilodaltons and the half-life increases from 3–8 hours to 65 hours. Other pharmacokinetic variables altered include a decreased volume of distribution (from 31–73 L to 8–12 L) and decreased systemic clearance (from 6.6–29.2 L/hour to 0.06–0.1 L/hour). The pharmacodynamic effects of antiviral and antitumor activities of pegylated IFN-α-2b are 12–136-fold and 18-fold, respectively, greater than the unpegylated form. The net result of these pharmacokinetic and pharmacodynamic improvements is that the frequency of pegylated IFN-α-2b administration for treating chronic hepatitis C is once weekly compared with three times weekly for the unpegylated form.

Hyperglycosylation. Hyperglycosylation is the addition of sugar moieties to proteins and can be engineered using molecular biology techniques to specific locations on a protein. Many cellular proteins have N-linked or O-linked glycan modification that are added in posttranslational and cotranslational processes in the endoplasmic reticulum and in the Golgi apparatus [37–39]. The N-linked glycosylations occur at amino groups of the asparagine in Asn-X-Ser/Thr sequences, although not all potential glycosylation sites may be modified and heterogeneity can occur within given protein molecules. The O-linked glycosylations occur at the hydroxyl groups of serine and threonine.

Receptor-Mediated Elimination. For some proteins, pharmacokinetic nonlinearities can occur because of receptor-mediated elimination. When therapeutic proteins bind their cognate cell-surface targets, the bound therapeutic protein can be internalized by receptor-mediated or fluid-phase endocytosis and traffic to the lysosomes where it may be degraded (Figure 3.2-2) [40]. The capacity-limited nature of these systems can manifest as saturable dose-dependent drug clearance and may be susceptible to further modulation through functional adaptation mechanisms such as receptor upregulation or downregulation. The saturable internalization of erythropoietin (EPO) in erythroid progenitor cells is a classic example [41]. Chapel et al. have shown that the bone marrow, a major site for erythropoietic cells, represents a significant EPO elimination pathway [42]. Busulfan or 5-fluoruracil-induced bone marrow ablation in sheep was associated with a decrease in EPO clearance, revealing the *in vivo* significance of target-mediated uptake and elimination for this therapeutic protein.

Complex target-mediated clearance mechanisms suggest that both pharmacokinetics and pharmacodynamics might have to be considered concurrently to understand the disposition of select macromolecules. Peptide and protein drugs that alter the expression of target cells may have the ability to modulate their pharmacokinetic properties. For example, thrombopoietin (TPO) is an endogenous hematopoietic growth factor that stimulates the proliferation and differentiation of megakaryocytes and thus the production of new platelets, which, in turn, would yield a net increase in the density of available TPO receptors (c-Mpl) and reconcile

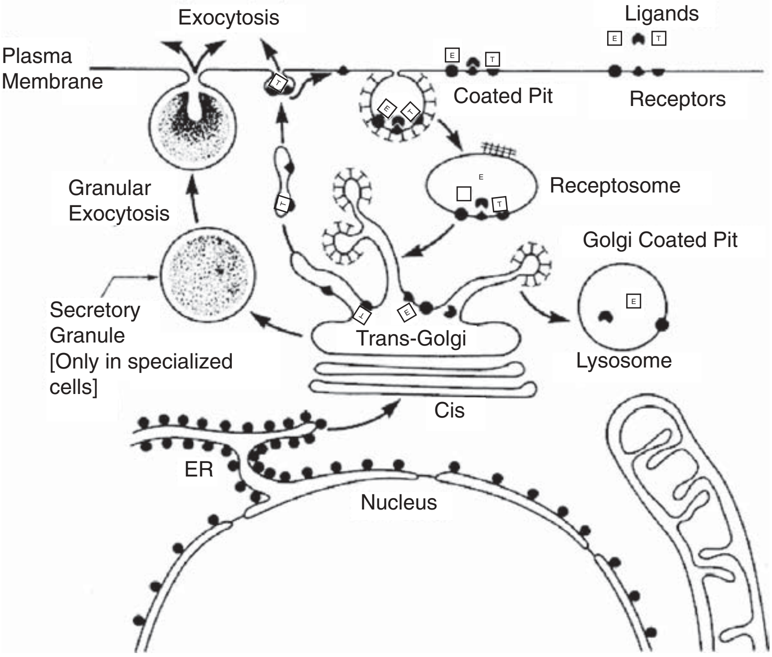

Figure 3.2-2. Schematic for the pathway of receptor-mediated endocytosis. Example ligands include EGF (E), transferrin (T), and α_2-macroglobuilin (●), and they are shown along with their respective receptors (●, ●, and ▲). These ligands are examples of systems in which both ligand and receptor are transferred to lysosomes (EGF), both ligand and receptor are recycled to the cell surface (transferrin), and the ligand is delivered to lysosomes but the receptor is efficiently recycled (α_2-macroglobuilin). For some systems, receptors may undergo significant turnover in the absence of ligand. (Figure and legend reproduced with permission [from Ref. 40].)

the reciprocal relationship between platelet count and circulating plasma TPO concentrations [43].

3.2.3 PHARMACOKINETIC DATA ANALYSIS

The primary objective of pharmacokinetic data analysis is to characterize quantitatively the drug disposition processes discussed in Section 3.2.2. Sufficient knowledge of the preclinical pharmacokinetics of macromolecules, which can only be obtained via mathematical formalisms, may be used to anticipate relevant pharmacokinetic properties in humans (Section 3.2.4), thereby serving to guide dose selection in subsequent clinical trials. The two most commonly used methods for characterizing pharmacokinetic data are noncompartmental analysis and compartmental modeling. Basic assumptions and techniques are presented in this section and are placed within the context of biotechnology pharmaceuticals, which may provide guidance for selecting the most appropriate and desirable method for a given dataset. It is important to recognize that no method of data analysis can offset

shortcomings in experimental designs and assays, and that careful consideration of such details is a sine qua non in pharmacokinetics [44].

3.2.3.1 Noncompartmental Analysis

Intravenous Drug Disposition. The estimation of primary pharmacokinetic parameters using noncompartmental analysis is based on statistical moment theory [45, 46]. The relationships defined by this theory are valid under the assumption that the system is linear and time-invariant. For simplicity, we further assume that drug is irreversibly removed only from a single accessible pool (e.g., plasma space). Regardless of the route of administration, the temporal profile of plasma drug concentrations, $C_p(t)$, can represent a statistical distribution curve. As such, the zeroth and first statistical moments (M_0 and M_1) are defined as:

$$M_0 = \int_0^\infty C_p(t)\,dt = AUC \tag{3.2-1}$$

$$M_1 = \int_0^\infty t \cdot C_p(t)\,dt = AUMC \tag{3.2-2}$$

where AUC and $AUMC$ are the so-called area under the plasma concentration-time curve and area under the first-moment curve. Several methods have been described for estimating the values of these moments, some of which will be presented in this section, and may be used to calculate relevant pharmacokinetic parameters.

Under linear conditions, the time-course of plasma drug concentrations following a single IV bolus dose can be characterized by a sum of exponentials:

$$C_p(t) = \sum C_i \cdot e^{-\lambda_i \cdot t} \tag{3.2-3}$$

where the coefficients (C_i) and exponentials (λ_i) may be obtained via curve-stripping, or more appropriately, from curve-fitting using nonlinear regression analysis. One advantage of fitting Equation (3.2-3) to pharmacokinetic data is the relative simplicity in calculating AUC and $AUMC$ values [47]:

$$AUC = \sum C_i / \lambda_i \tag{3.2-4}$$

$$AUMC = \sum C_i / \lambda_i^2 \tag{3.2-5}$$

Primary pharmacokinetic parameters such as total systemic clearance (CL) and the volume of distribution at steady state (V_{ss}) can be defined as:

$$CL = D_{iv} / AUC \tag{3.2-6}$$

and

$$V_{ss} = \frac{D_{iv} \cdot AUMC}{AUC^2} = CL \cdot MRT_{iv} \tag{3.2-7}$$

where D_{iv} represents the IV bolus dose and MRT_{iv}, or mean residence time, is the average time a drug molecule resides in the system before being irreversibly removed. Also, the central volume of distribution (V_c) can be calculated as:

$$V_c = D_{iv} \Big/ \sum C_i \tag{3.2-8}$$

Additional advantages to resolving AUC and $AUMC$ from curve-fitting the sums of exponentials are the stability of the estimates and that nonlinear regression procedures provide measures of error about the pharmacokinetic parameter estimates.

Peptide and protein drugs requiring an IV route of administration may also be given as a constant rate infusion. Pharmacokinetic data from experiments designed to achieve a steady-state plasma concentration (C_{ss}) allow for the direct calculation of drug clearance according to the equation:

$$CL = k_0 / C_{ss} \tag{3.2-9}$$

where k_0 is the constant zero-order rate of drug infusion. The steady-state volume of distribution can be obtained from:

$$V_{ss} = \frac{k_0 \cdot T - CL \cdot AUC_0^T}{C_{ss}} \tag{3.2-10}$$

where T is the duration of the IV infusion. For short-term constant rate infusions, when plasma concentrations do not attain C_{ss}, Equation (3.2-6) is valid for calculating clearance by substituting $k_0 \cdot T$ for D_{iv}. Moment analysis also may be used to generate V_{ss} under these conditions from the equation:

$$V_{ss} = \frac{k_0 \cdot T \cdot AUMC}{AUC^2} - \frac{k_0 \cdot T^2}{2 \cdot AUC} \tag{3.2-11}$$

Extravascular Drug Disposition. In general, peptide and protein drugs exhibit poor systemic bioavailability following oral administration owing primarily to gastrointestinal enzymatic degradation. On the other hand, IV drug administration may not result in a desirable time-course of drug exposure and certainly lacks appeal for patients requiring chronic therapy. One of the most common routes of extravascular peptide and protein drug administration is subcutaneous injection, with additional routes, such as inhalation, intranasal, and transdermal delivery representing the targets of current investigation [48].

The time-course of plasma drug concentrations following extravascular administration is often irregular, and simple analytical solutions for calculating AUC and $AUMC$, such as Equations (3.2-4) and (3.2-5), are not readily available. For these cases, numerical integration methods may be used to evaluate the integrals in Equations (3.2-1) and (3.2-2), such that:

$$AUC = \int_0^{t^*} C_p(t)dt + \frac{C_p^*}{\lambda_z} \tag{3.2-12}$$

and

$$AUMC = \int_0^{t^*} t \cdot C_p(t)dt + \frac{t^* \cdot C_p^*}{\lambda_z} + \frac{C_p^*}{\lambda_z^2} \tag{3.2-13}$$

where C_p^* and t^* are the last observed plasma concentration and time values, respectively, λ_z is the terminal slope of the curve, and the quotients provide estimates of the area extrapolating from t^* to infinity. The trapezoidal and log-trapezoidal rules are the most common methods for numerically evaluating the integrals in Equations (3.2-12) and (3.2-13) [49]. The trapezoidal rule for calculating the area under a curve within an interval t_i and t_{i-1} is given as:

$$\int_{i-1}^{i} y \cdot dy = 0.5 \cdot [(y_i + y_{i-1})(t_i - t_{i-1})] \tag{3.2-14}$$

where y is $C_p(t)$ for AUC and $t \cdot C_p(t)$ for $AUMC$. For the log-trapezoidal rule, the equation is:

$$\int_{i-1}^{i} y \cdot dy = \frac{1}{\ln\left(\frac{y_i}{y_{i-1}}\right)} \cdot [(y_i + y_{i-1})(t_i - t_{i-1})] \tag{3.2-15}$$

The cumulative sum of the interval areas thus provides an estimate of the AUC and $AUMC$ from time zero to t^*. Yu and Tse have evaluated the performance of several numerical integration algorithms for calculating AUC [49]. In practice, it is most common to employ the trapezoidal rule for ascending ($y_i > y_{i-1}$) and plateau ($y_i \approx y_{i-1}$) regions of the curve and the log-trapezoidal rule when measured values are decreasing ($y_i < y_{i-1}$). Such an approach is used for noncompartmental analysis in the computer program WinNonlin (Pharsight, Mountain View, CA), a nonlinear regression analysis program specifically designed for pharmacokinetic and pharmacodynamic data analysis.

The noncompartmental analysis of pharmacokinetic data after extravascular drug administration, when coupled with that of IV dosing, can yield additional relevant pharmacokinetic parameters, particularly regarding absorption processes. For example, the systemic availability (F), which represents the net fraction of the drug dose reaching the systemic circulation after extravascular administration, is defined as:

$$F = \frac{D_{iv} \cdot AUC_{ev}}{D_{ev} \cdot AUC_{iv}} \tag{3.2-16}$$

where catabolism at the extravascular site of administration and other processes may result in incomplete drug absorption. Also, the mean absorption time (MAT), or the average time a drug molecule remains unabsorbed, can be calculated from the relationship:

$$MAT = MRT_{ev} - MRT_{iv} \tag{3.2-17}$$

where the mean residence times derive from the ratios of *AUMC* and *AUC* [e.g., Equation (3.2-7)].

Overall, the relative simplicity of noncompartmental analysis, as compared with the methodological challenges of developing and validating structural mathematical models [50], forms the basis for it being the most common method for ascertaining the major pharmacokinetic properties of drugs. It is beyond the scope of this chapter to contrast the merits of these two methods, and the reader is referred to more complete treatments and the references therein [44, 51]. However, as discussed in Section 3.2.2, various pharmacokinetic processes of many peptide and protein pharmaceuticals are inherently nonlinear, which violate the fundamental assumptions of linearity and time-invariance in statistical moment analysis. For such compounds, the construction of mechanism-based mathematical models is required and essential for characterizing the *in vivo* pharmacokinetics of the drug (Section 3.2.3.2). In any event, noncompartmental analysis represents a highly useful starting point for any pharmacokinetic data analysis [44]. For simple linear systems, this technique may be sufficient for calculating primary pharmacokinetic parameters from preclinical experiments and anticipating dose-concentration relationships in humans (Section 3.2.4.1). Additionally, moment analysis of plasma concentration-time profiles resulting from a suitable range of dose levels may be used initially to identify whether nonlinearities exist, such as disproportionate *AUC* values (relative to dose) indicating dose-dependent clearance or bioavailability, thus necessitating the implementation of more sophisticated methods of pharmacokinetic systems analysis.

3.2.3.2 Pharmacokinetic Models

Compartmental modeling involves the specification of a structural mathematical model (commonly using either explicit or ordinary differential equations) and system parameters are estimated from fitting the model to pharmacokinetic data via nonlinear regression analysis or population mixed effects modeling. The methodological issues involved in the development, application, and interpretation of pharmacokinetic models are beyond the scope of this chapter and are discussed in detail elsewhere [50, 52]. The most popular structural model applied to macromolecule pharmacokinetic data is the open two-compartment model shown in Figure 3.2-3. This system is described, in general, by the following differential equations:

$$\frac{dA_p}{dt} = \frac{Input}{V_c} - \left(\frac{CL}{V_c} + \frac{CL_D}{V_c}\right) \cdot A_p + \frac{CL_D}{V_t} \cdot A_t \tag{3.2-18}$$

$$\frac{dA_t}{dt} = \frac{CL_D}{V_c} \cdot A_p - \frac{CL_D}{V_t} \cdot A_t \tag{3.2-19}$$

where A_i represents the amount of drug in the plasma ($i = p$) or tissue ($i = t$) compartments, *Input* represents a function describing the appearance of drug based on the route of drug administration, CL_D is the distributional clearance between compartments, and V_t is the volume of the second or tissue compartment. Plasma drug concentrations are thus specified as $C_p = A_p/V_c$.

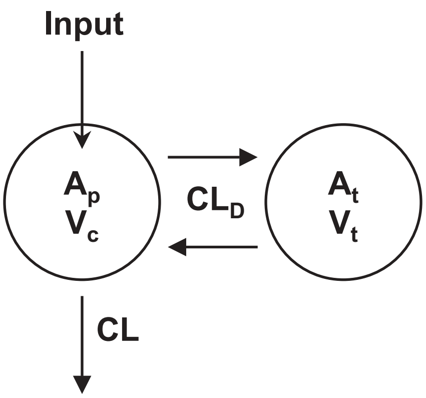

Figure 3.2-3. Schematic of a two-compartment mammillary model commonly used to characterize macromolecule pharmacokinetics. Drug input and elimination (CL) occur to and from a central compartment (A_p) and may distribute (CL_D) to a peripheral site (A_t, V_t). Plasma drug concentrations reflect the amount in the central compartment relative the volume of distribution of that site (V_c).

TABLE 3.2-1. Input Functions for Specific Pharmacokinetic Applications

D, dose; F, bioavailability; fr, fraction of dose undergoing first-order input in a dual absorption model; K_0, zero-order input rate; k_a and k'_a, first-order absorption rate constants; MAT, mean absorption time; NV^2, normalized variance of Gaussian density function, t, nominal time; t_{lag}, duration of time-lag; τ, duration of rapid input in dual absorption model; T_{inf}, duration of zero-order IV infusion; T, modulus time.

Condition	Input Function		Equation
Rapid intravenous injection	0		—
Intravenous infusion	K_0	$t \le T_{inf}$	—
	0	$t > T_{inf}$	
Linear first-order absorption with a time-lag	0	$t \le t_{lag}$	3.2-20
	$F \cdot D \cdot k_a \cdot e[-k_a \cdot (t - t_{lag})]$	$t > t_{lag}$	
Two consecutive first-order processes	$F \cdot D \cdot \frac{k_a \cdot k'_a}{(k'_a - k_a)} \cdot [e(-k_a \cdot t) - e(-k'_a \cdot t)]$		3.2-21
Rapid zero-order input followed by linear first-order absorption	$F \cdot D \cdot (1 - fr)/\tau$	$t \le \tau$	3.2-22
	$F \cdot D \cdot fr \cdot k_a \cdot e[-k_a \cdot (t - \tau)]$	$t > \tau$	3.2-23
Inverse Gaussian	$F \cdot D \cdot \sqrt{\frac{MAT}{2\pi \cdot NV^2 \cdot T^3}} \cdot e\left[-\frac{(T - MAT)^2}{2 \cdot NV^2 \cdot MAT \cdot T}\right]$		3.2-24

The drug input function in Equation (3.2-18) will depend on the experimental design and several common functions are listed in Table 3.2-1. For rapid IV injection, the input function is set equal to zero and the dose (D) is reflected in the initial condition for Equation (3.2-18) [$A_p(0) = D$]. A constant rate IV infusion also is easily handled by setting *Input* equal to the zero-order infusion rate (K_0) for time

(t) less than or equal to the infusion time (T_{inf}), otherwise $Input = 0$. The remaining equations in Table 3.2-1 typically are used to describe extravascular drug administration. The simplest function [Equation (3.2-20)] assumes a linear first-order absorption process (k_a) from an extravascular site following a short time-lag (t_{lag}). If a time-lag is not observed, t_{lag} may be set to zero, resulting in a simple linear absorption model, as exemplified in a pharmacokinetic model for recombinant human growth hormone following SC dosing in monkeys [53]. As mentioned in the previous section, IV pharmacokinetic data must be analyzed simultaneously with SC data to estimate drug bioavailability (F).

Owing to the complexities of drug absorption from extravascular sites (see Section 3.2.2.1), peptide and protein drugs may require an additional delay compartment [Equation (3.2-21)] comprising two consecutive first-order processes [54, 55], which may be accompanied by an initial rapid input of a fraction of the dose as defined by Equations (3.2-22) and (3.2-23). Such a dual absorption model was used to describe the input of recombinant erythropoietin after SC administration in monkeys [56]. Interestingly, the bioavailability was shown to be dose-dependent and ranged from 0.268 to 1.0, increasing with increased dose level. This property may be caused by saturation of catabolism at the site of drug administration; however, further research is needed to elucidate the specific processes involved in drug disposition following extravascular dosing. Many other complex functions are available, such as an inverse Gaussian model [Equation (3.2-24)], which may be substituted into pharmacokinetic models to describe the absorption of macromolecules.

The clearance of several macromolecules may be characterized using simple linear first-order elimination as shown in Equation (3.2-18) [53, 57], but may depend on the animal species and range of dose levels being evaluated. In contrast, many peptide and protein drugs demonstrate saturable or capacity-limited clearance, and CL in Equation (3.2-18) may be defined with a concentration-dependent function, such as:

$$CL = \frac{V_{\max} \cdot V_c}{K_m \cdot V_c + A_p} + CL_{ns} \tag{3.2-25}$$

where $V_{\max}$ and K_m are the traditional Michaelis–Menten parameters and CL_{ns} represents a linear nonsaturable clearance pathway. The nonlinear Michaelis–Menten function [quotient in Equation (3.2-25)] may be specified alone [56] or in parallel with CL_{ns} [58, 59]. Thus, at high plasma drug concentrations (i.e., $C_p >> K_m$), the saturable clearance function approaches a limiting value ($V_{\max}$), and at relatively low concentrations will represent a first-order elimination rate ($V_{\max}/K_m$).

Receptor-mediated clearance is an example of target-mediated drug disposition (TMDD), where binding of a compound to a pharmacological target (e.g., enzyme, receptor, or other proteins) influences the pharmacokinetics of the drug [60]. Such systems often exhibit a dose-dependent decrease in the apparent volume of distribution (approaching a limiting value). The general pharmacological expectations of TMDD and techniques for characterizing this phenomenon have been reviewed recently [61]. A general pharmacokinetic model of TMDD has been described [62], and the operative equations defining the rate of change of plasma drug concentrations typically include:

$$\frac{dC_p}{dt} = -k_{on} \cdot R_f \cdot C_p + k_{off} \cdot RC \quad (3.2\text{-}26)$$

$$\frac{dRC}{dt} = k_{on} \cdot R_f \cdot C_p - (k_{off} + k_{\text{int}}) \cdot RC \quad (3.2\text{-}27)$$

where k_{on} and k_{off} are second- and first-order rates of association and dissociation, R_f and RC represent free and bound receptor (or pharmacological target) concentrations, and k_{int} is a first-order internalization rate constant of RC. Under certain conditions, the total receptor concentration (R_{tot}) may be assumed to be time-invariant [11, 62], and thus $R_f = R_{tot} - RC$. Therefore, at high drug concentrations, $RC \to R_{tot}$ and effectively limits the distribution and elimination of drug from the central compartment. This approach has been used to characterize the complex nonlinear pharmacokinetics and pharmacodynamics of IFN-β 1a in monkeys [54]. Alternatively, an additional equation may be introduced that describes the rate of change of R_f directly [55]. Also, an equilibrium solution to the general TMDD model is available, where the drug-binding microconstants (k_{on} and k_{off}), which are often difficult to estimate from routine pharmacokinetic data, are replaced with an equilibrium dissociation constant ($K_D = k_{off}/k_{on}$) [63].

3.2.4 PREDICTING MACROMOLECULE PHARMACOKINETICS IN HUMANS

One of the major goals of preclinical pharmacokinetics is to obtain relevant information on the *in vivo* disposition of drugs early in the drug development process and to apply such knowledge to anticipate probable pharmacokinetic properties in humans for initial dose selection in phase I clinical trials. Allometric scaling and physiologically based pharmacokinetic (PBPK) models are the most popular techniques for predicting pharmacokinetic properties of drugs in one species from data collected in one or more other species. Although these methods have been applied to small-molecular-weight compounds for decades with variable and often limited success, it is hypothesized that these techniques are more accurate for peptide and protein drugs owing to the relative species conservation of mechanisms that control the biodistribution and elimination of such compounds [64, 65].

3.2.4.1 Allometric Scaling

Many physiological processes and organ sizes scale across species according to the well-known power-law relationship or allometric equation [66]:

$$Y = a \cdot W^b \quad (3.2\text{-}28)$$

where Y is a physiological parameter of interest, W represents body weight, and a and b are the allometric coefficient and exponent. The linearized form of Equation (3.2-28) is obtained by taking its logorithm:

$$\log Y = \log a + b \cdot \log W \quad (3.2\text{-}29)$$

where log a and b represent the intercept and slope of the physiological data presented on a log-log plot. The units of a will depend on the units of Y and W, and its absolute value will depend on the specific property of interest. In contrast, b is a unitless parameter characterizing the rate of change of Y with respect to W. According to the power-law relationship, Y may increase more rapidly than W ($b > 1$), less rapidly than W ($0 < b < 1$), or be directly proportional ($b = 1$). For rates of metabolism and clearance processes, the allometric exponent tends to be around 0.75, whereas organ sizes or physiological volumes tend to be proportional to body weight [66]. Physiological times or the duration of physiological events (e.g., heartbeat and breath duration, lifespan, or turnover times of endogenous substances or processes) scale across species with b values around 0.25 [66, 67]. These interspecies relationships appear to manifest from the fractal nature of biological systems [68, 69].

Retrospective analysis suggests that primary pharmacokinetic parameters of many small synthetic molecules scale across species according to allometric principles, primarily reflecting the physiological processes controlling such characteristics [67, 70]. However, the use of allometric scaling for prospective predictions of human pharmacokinetic parameters and dose selection of these compounds is controversial and is the topic of considerable debate [71, 72]. In addition, several correction factors and techniques have been suggested for improving the prediction of drug clearance in humans from preclinical values [73, 74]. Few studies have been conducted that specifically address the role of parameter uncertainty and species selection; however, those that have been reported suggest careful study designs and caution for prospective allometric scaling predictions [75, 76]. Research directed toward improving the understanding of interspecies pharmacokinetic relationships is likely to continue and necessary for resolving key methodological issues.

Notwithstanding concerns associated with prospective allometric scaling, primary pharmacokinetic parameters of select macromolecules appear to follow allometric relationships [65, 77–81], possibly resulting from a conservation of processes controlling peptide and protein disposition [64, 65]. Mahmood reviewed the prediction of total clearance of 15 therapeutic proteins from interspecies scaling, confirming the need for a suitable number of animals and that simple allometry may be used for most proteins [82]. As an example, Figure 3.2-4 shows log-log plots of total systemic clearance and the volume of distribution at steady state for interferon-α in mice, rats, rabbits, dogs, monkeys, and humans [78]. The lines of regression were generated without considering human values and the relationships were as follows: $CL = 3.7W^{0.71}$ ($r^2 = 0.98$) and $V_{ss} = 0.2W^{0.94}$ ($r^2 = 0.99$). Typical values in man (open symbols) were slightly underestimated using these equations, and Lave et al. suggest that transformations of plasma concentration-time profiles make more use of preclinical data and may provide improved predictions of human pharmacokinetic parameters [78]. Building on this concept, Cosson et al. described a method of fitting preclinical pharmacokinetic profiles and estimating allometric relationships simultaneously using a population mixed effects modeling technique [83]. Such an approach has been applied to characterize the interspecies pharmacokinetic relationships of pegylated human erythropoietin [84]. The final model was used to predict typical pharmacokinetic parameters in humans, as well as to simulate expected concentration-time profiles from IV and SC administration.

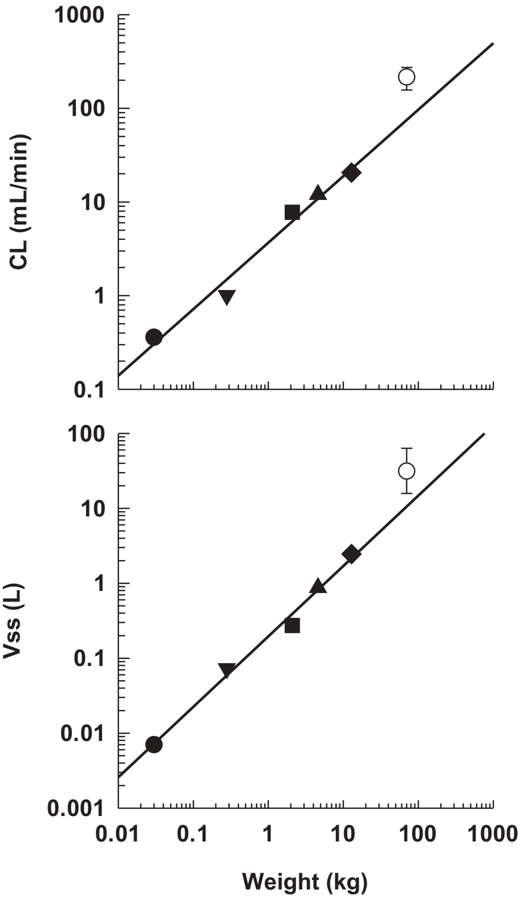

Figure 3.2-4. Interspecies scaling of total systemic clearance (*CL*; top panel) and steady-state volume of distribution (V_{ss}; bottom panel) of interferon-α as a function of total body weight. Species include mouse (●), rat (▼), rabbit (■), African green monkey (▲), dog (◆), and human (○). Human values were not included in the line of regression, and data were obtained from Lave et al. [78].

Despite successful applications of interspecies scaling to macromolecule pharmacokinetics, potential complicating factors exist, the most significant of which relate to saturable or dose-dependent pharmacokinetic processes. As discussed in Section 3.2.2, nonlinear behavior may manifest from several sources including receptor capacity and binding kinetics, macromolecule physico-chemical properties, and major mechanisms of peptide and protein transport and elimination. Thus, evidence of nonlinear pharmacokinetics in preclinical experiments would raise concerns as to the utility of allometric scaling for predicting such properties in humans. It remains to be determined whether a combination of *in vivo* preclinical data, compartmental modeling, and *in vitro* uptake studies might reliably anticipate macromolecule pharmacokinetics in humans under such nonlinear conditions [85].

3.2.4.2 Physiologically Based Pharmacokinetic Modeling

Classic pharmacokinetic modeling attempts to characterize drug disposition with systems comprised of a relatively small number of compartments (see Section 3.2.3.2). In contrast, PBPK models seek to mimic physiological pathways and processes controlling the time-course of plasma drug concentrations and represent the state-of-the-art in advanced pharmacokinetic systems analysis. As Dedrick has noted, "Physiologic modeling enables us to examine the joint effect of a number of complex inter-related processes and assess the relative significance of each" [86]. Basic concepts of PBPK modeling and applications to macromolecule pharmacokinetics are described in this section, and several reviews may be consulted for further details regarding the specification, implementation, and evaluation of PBPK models [87, 88].

The compartments in PBPK models represent organs and tissues of interest and are arranged and connected according to anatomical and physiological relationships (Fig. 3.2-5). Most PBPK models contain principal components, such as arterial and venous blood pools, liver, and kidney, along with additional tissues depending on its role in specific disposition processes (e.g., absorption, transport, and elimination), whether it represents a potential site of action (biophase) or is likely to account for a significant proportion of the administered dose [88]. A series of mass-balance equations are specified that define the time-course of drug concentrations within each compartment. In the simplest case, it is assumed that mass

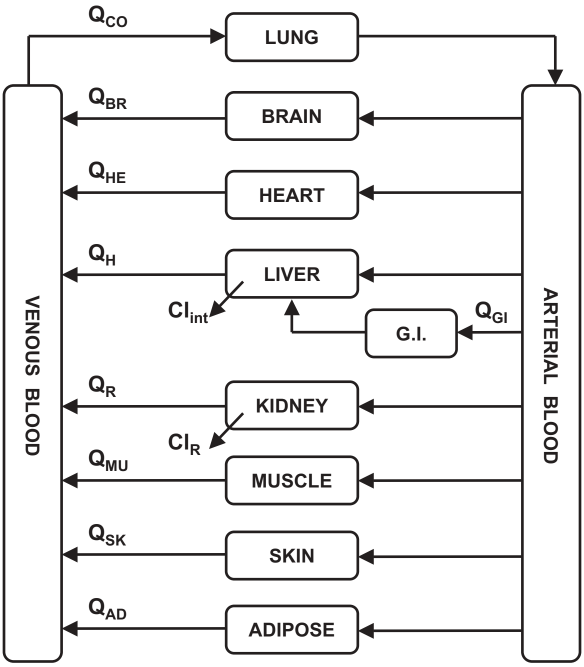

Figure 3.2-5. Model structure of a hypothetical physiologically based pharmacokinetic model. Tissue blood flows are shown (Q) along with renal (Cl_R) and nonrenal (Cl_{int}) drug clearance pathways.

transfer is blood-flow or perfusion-rate limited and compartments are well-stirred spaces. Under this assumption, the rate of change of drug concentration (C) in a noneliminating tissue (T) may be described by the following ordinary differential equation:

$$V_T \cdot dC_T / dt = Q_T \cdot (C_A - C_T / K_{pT}) \tag{3.2-30}$$

where V and Q represent the volume and blood flow associated with a particular tissue, K_p is the tissue:plasma partition coefficient, and C_A is arterial drug concentration. Drug elimination (via excretion or metabolism) in specific organs often is described using a first-order approximation or a Michaelis–Menten function, separately or in parallel [Equation (3.2-25)]. Physiological parameters (e.g., V and Q) are frequently fixed to experimentally-measured values or literature-reported estimates [89, 90]; however, these terms have also been estimated during model fitting with a Maximum *a Posteriori* Bayesian method [91]. Several *in vitro* and *in vivo* experimental methods have been described for determining drug-specific parameters [92, 93]. Again, most contemporary applications of PBPK modeling involve estimating such terms from fitting the model to pharmacokinetic data.

Sugiyama and Hanano constructed a simple "minimal" PBPK model, consisting of plasma, liver, and kidney compartments, to evaluate the role of receptor-mediated clearance in the overall disposition of epidermal growth factor (EGF) in rats [11]. A remainder compartment was included to account for the rest of the body of the animal. The kinetics of the liver compartment incorporated receptor turnover processes (i.e., synthesis and degradation), binding of drug to free cell-surface receptors, and internalization of the drug-receptor complex (endocytosis and degradation). Computer simulations were conducted to evaluate this model, revealing that nonlinear kinetics of EGF may result from capacity limitation produced by either a saturation of free receptors or dose-dependent receptor downregulation.

The simple assumptions that constitute blood-flow-limited PBPK models often are inadequate for characterizing the pharmacokinetics of macromolecules. Instead, a membrane- or permeability-rate-limited model is more common, where it is assumed that mass transfer across the cell membrane is rate-limiting. For these models, organ compartments are subdivided into at least two well-stirred spaces representing vascular ($C_{T,V}$) and extravascular ($C_{T,EV}$) compartments. Such a system might be described by the following equations for a noneliminating tissue:

$$V_{T,V}\, dC_{T,V} / dt = Q_T \cdot (C_A - C_{T,V}) - f_{uB} \cdot PS_T \cdot (C_{T,V} - C_{T,EV} / K_{pT}) \tag{3.2-31}$$

$$V_{T,EV}\, dC_{T,EV} / dt = f_{uB} \cdot PS_T \cdot (C_{T,V} - C_{T,EV} / K_{pT}) \tag{3.2-32}$$

where f_{uB} is the free fraction in blood and PS_T is the permeability surface area product. Examples of membrane-limited models developed for protein molecules include β-endorphin, a 31 amino acid straight-chain polypeptide [94], and ISIS 1082, a 21-mer phosphorothioate oligonucleotide [95].

Monoclonal antibodies represent a diverse group of therapeutic proteins typically presenting with complex pharmacokinetic properties [10]. For these compounds, more comprehensive, mechanism-based PBPK models have been described [96, 97]. Baxter et al. developed and evaluated a bifunctional antibody PBPK model in mice and scaled the model to predict its pharmacokinetics in humans [96]. A membrane-

limited model was used; however, additional equations were required to describe up to nine molecular species in each tissue (resulting from specific and nonspecific binding), and mass transport across the membrane included convective and diffusive components (so-called two-pore system). The latter model, by Friedrich et al., further incorporated lymphatic circulation and identified critical properties requiring optimization for this treatment modality to be successful [97].

Although the PBPK approach has existed for several decades, reports of its use in characterizing macromolecule pharmacokinetics have been relatively sparse. The technological requirements for PBPK modeling are often seen as formidable; however, advances in computer hardware and software are bringing this methodology within common reach. The significant potential for scaling preclinical models to anticipate human pharmacokinetics in various relevant tissues (including target sites) represents a strategic advantage of PBPK modeling in drug development. Furthermore, this systems approach provides a means of understanding the pharmacological implications of the complexities associated with the disposition of macromolecules.

3.2.5 CONCLUSIONS

The pharmacokinetic properties of biotechnology pharmaceuticals are complex relative to small-molecule drugs, and preclinical studies are critical to the discovery and development of these therapeutic agents [98]. Understanding the mechanisms and implications of *in vivo* disposition of macromolecules provides a means for investigating and designing novel drug candidates and delivery systems to optimize exposure-response relationships or therapeutic efficacy. Mathematical modeling of preclinical pharmacokinetic data is necessary for characterizing such properties, and techniques like allometric scaling and PBPK modeling may be used to anticipate human pharmacokinetics under certain conditions. The utility of these approaches may be further enhanced by coupling pharmacokinetic data with mechanism-based pharmacodynamic modeling of biomarkers and surrogates of drug effects [8, 99, 100].

3.3.1 INTRODUCTION

The advent of molecular biology and genetics has identified numerous biotechnology-derived macromolecular drugs as potential targets for development. The factors required for the development of this new class of drugs are, however, significantly different from those required for conventional drug compounds with molecular weight less than 1 kDa or so [1, 2]. Efforts directed toward the delivery of small

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

molecules have largely sought a compromise between two major factors, i.e., aqueous solubility and membrane partition properties. On the other hand, not only does the primary structure of proteins and genes require protection from enzymatic degradation but also higher order structures from denaturation [3]. In addition, for many macromolecules with therapeutic potential, be it peptide or protein-based drugs or nucleic acid-based drugs such as antisense oligonucleotides, ribozymes, siRNA, aptamers, and plasmid DNA, delivery to the cytosol becomes a necessary, if not sufficient, condition for their full pharmacological activity. For example, antisense oligomers or siRNA, which are extensively sequestered in endosomes after cellular uptake, require cytosolic delivery to bind ribosomal mRNA/nuclear pre-mRNA in order to inhibit protein translation or correct splicing [4–6]. As a result, several strategies to promote the cytosolic delivery of macromolecular therapeutics have been developed over the past few years. We have classified these diverse strategies into (1) those that exploit the biochemical aspects of the endosomal lumen to promote endosome-to-cytosol transfer and (2) approaches that bypass the endocytic pathway by facilitating direct transport of macromolecules across the plasma membrane.

3.3.2 ENDOSOME-TO-CYTOSOL TRANSFER

The plasma membrane is a mosaic network of lipids and proteins decorated with complex carbohydrates. This 5–10-nm-thick lipid bilayer is burdened with the dual role of serving as a barrier to external agents, while regulating the entry of nutrients into the cell. Conventional small molecules, such as amino acids, sugars, and ions, generally traverse the plasma membrane through a con-certed function of integral membrane protein carriers or channels. However, macromolecules, by virtue of their polarity and large hydrodynamic diameter, are taken up in membrane-bound vesicles derived by the invagination and pinching-off of sections of the plasma membrane in a process termed endocytosis. Endocytosis can occur via multiple mechanisms that can be broadly classified into (1) phagocytosis or the uptake of large particles and (2) pinocytosis or the uptake of fluid and solutes. Phagocytosis is typically restricted to specialized mammalian cells, such as macrophages and other antigen presenting cells, whereas pinocytosis occurs in all cells by at least four known mechanisms: macropinocytosis, clathrin-mediated endocytosis, caveolae-mediated endocytosis, and clathrin- and caveolae-independent endocytosis [7].

Internalization of macromolecules and a variety of pathogens via caveolae is another endocytic mechanism alternative to the clathrin-mediated process. Originally discovered in the 1950s, caveolae are uncoated, 50–100-nm flask-shaped invaginations of the plasma membrane. The process shares several similarities with clathrin-mediated typical endocytosis in that docking and fusion proteins involved in the latter are also found in caveolae. However, an important difference, especially from the perspective of delivery of intact therapeutic macromolecules, is the finding that the resulting “caveosomes” can avoid the degradative route to lysosomes [8]. Mechanistic aspects of such diverse and highly regulated endocytic pathways are beyond the scope of this review and discussed elsewhere. Nevertheless, three biochemical traits of endocytic vesicles or endosomes are particularly relevant in the context of macromolecular drug delivery.

First and foremost, it is well documented that the endosomal compartments maintain an acidic internal pH ranging from pH 5.5 to 6.5 and seem to mature or fuse with lysosomes, which maintain a lower pH (~5.0 to 5.5). This is vital for sorting of ligand-receptor complexes and the activation of hydrolytic enzymes such as cathepsins. Although the H^+-ATPase pumps protons into the endosome, the Na^+/K^+-ATPase acts to limit proton pumping into the endosomal compartment. In its normal orientation, the pump generates a positive interior membrane potential by pumping three Na^+ ions into the endosome for every two K^+ ions pumped out, thereby regulating the proton-translocating activity of the membrane bound H^+-ATPase. Evidence supporting these events has been provided by the treatment of isolated endosomes with inhibitors of Na^+/K^+-ATPase such as ouabain, which causes a fall in the pH within the endosomal compartments. Lysosomes, on the other hand, seem to lack Na^+/K^+-ATPase, and their luminal acidification is mainly regulated by H^+-ATPases.

Second, of several proteases that are known to participate in peptide/protein hydrolysis, the cysteine and aspartic proteases, also known as cathepsins, constitute a majority of the endosomal/lysosomal proteolytic machinery. These enzymes are often synthesized in an inactive form requiring excision of the pro-domain facilitated by other proteases or autocatalytic mechanisms activated by acidic pH. Cathepsins seem to have originally evolved to catabolize both internalized and endogenous proteins crucial for cellular homeostasis, autophagy, apoptosis, and antigen presentation. The optimal pH range for enzymatic activity of cathepsins ranges from 5.0 to 6.5, as is the case with endosomes/lysosomes.

Last, several redox pathways are thought to function within endosomes and lysosomes, although the exact mechanism(s) of disulfide reduction within the endosomal lumen are not well understood. Primary evidence stems from antigen processing within the endocytic pathway, which involves partial denaturation of internalized proteins facilitated in part by the acidic pH. Disulfide bonds, however, are not susceptible to lysosomal proteolysis and remain chemically stable at acidic pH. Disulfide reduction within endosomes/lysosomes has been attributed to active transport of cysteine (free thiol form) into lysosomes and redox enzymes such as γ-Interferon-inducible lysosomal thiol reductase (GILT) that function at an acidic pH optimum [9]. However, a recent report disputes the long-held view that endosomes and lysosomes are reductive environment. Rather, the experimental data support that they may exhibit an oxidizing environment suggesting that disulfide-based systems may function via a nonreductive mechanism or that they may be reduced in the cytosol after discharged from the endosome [10]. Overall, strategies for the endosome-to-cytosol transfer of macromolecular drugs can broadly be classified on the basis of the three aforementioned characteristics of the endosomal lumen, namely, acidic pH, proteolytic activity of cathepsins, and disulfide bond reduction.

3.3.2.1 pH-Sensitive Drug Carriers

Viruses have evolved proteins that perturb the host cell membrane by fusion. Stemming from this knowledge is the creation and use of pH-dependent fusogenic peptides. For example, diINF-7 is one such peptide that resembles the amino-terminal domain of the influenza virus hemagglutinin HA-2 subunit. At an endosomal pH of 5.0, the peptide undergoes a conformational change allowing it to penetrate

deeper into the endosomal membrane resulting in membrane destabilization [11]. The pH-sensitive behavior of viral peptides and bacterial proteins originates from that of weak acids with pKa values in the range of 4.5 to 7.0, primarily Glu residues with a pKa of approximately 5.0. Thus, the pH-dependent membrane partitioning or the partition coefficient of weak acids (with elevated membrane-bound pKa values) depends critically on the endosomal pH. Although the negatively charged side chains of the Glu residues in viral peptides such as INF-7, initially repel each other, they collapse into a hydrophobic α-helix due to protonation of the side-chain carboxylate ions at a pH close to their pKa. Subsequently, the helical peptide inserts itself into the endosomal membrane and leads to fusion or pore formation and eventually endosomal release. Based on these principles, Li et al. designed the GALA peptide, which consists of repeats of the peptide motif Glu-Ala-Leu-Ala and adapts a α-helical conformation at acidic pH [12]. The peptide was subsequently found to efficiently release calcein from phosphatidylcholine liposomes in a pH-specific manner, presumably via formation of pores or perturbation-mediated flip-flop of lipids.

Weak acid-based homopolymers such as poly(Glu) and poly(alkylacrylic acid) have been shown to disrupt membranes in a pH-dependent manner [13, 14]. Poly(ethylacrylic acid) is thought to form cation-selective aqueous pores in lipid bilayers at relatively low concentrations, providing a potential application in promoting endosome-to-cytosol transfer of macromolecules. Mechanistically, the carboxylate head groups become neutral at a pH < pKa triggering polymer contact with endosomal membranes, resulting in membrane permeabilization. Polycationic molecules have been extensively used to promote the cellular delivery of macromolecules, due to their potent membrane disruptive, destabilizing, or fusogenic activity. A proton gradient such as the one found in endosomes and lysosomes can be exploited to protonate weakly basic drug carriers with pKa values between 5.0 and 7.0. The cationic charge thus generated can induce dramatic changes in the physico-chemical properties of the carrier.

Poly(His) was perhaps the first pH-sensitive polymer shown to promote fusion between lipid bilayers [15]. The imidazole functionality in the side chain of the His residue is protonated at low pH, and it interacts with negatively charged head groups of lipids. Although proximity-driven lipid and content mixing is observed at lower concentrations, a higher concentration of the polymer causes disruption of the bilayer and leakage of contents. Imidazole-containing polymers and their endosomolytic properties have received much attention lately, as exemplified by a pH-sensitive His-containing peptide analogous to the influenza HA-2. Histidylated polylysine and gluconic acid modified poly(His) have also been shown to promote efficient gene transfer [16]. Lee et al. constructed a core-shell-type micelle from the two block copolymer components poly(L-histidine)-*b*-poly(ethylene glycol) and poly(L-lactic acid)-*b*-PEG-*b*-polyHis-biotin and showed that after biotin receptor-mediated endocytosis, the micelle exhibited pH-dependent dissociation, thus allowing for the release of the model drug doxorubicin to be released in the early endosomal pH [17]. Furthermore, the collapsed micellar components could subsequently destabilize the endosomal membrane allowing for doxorubicin to enter the cytosol.

Polyethyleneimine (PEI) and starburst dendrimers are other examples of pH-sensitive cationic polymers, which become protonated incrementally over a wide

pH range [18, 19]. The application of these pH-sensitive cationic polymers to oligonucleotide and gene delivery has been studied extensively. Other examples of the use of pH-sensitive materials are hydrogels made of chitosan and copolymers of chitosan [20]. These represent a class of polymeric delivery systems used for controlled drug release. Hydrodynamic swelling or shrinking of these gel-like polymers at low pH (due to protonation of the polymer side-chain moieties) is thought to release the entrapped contents. The proton sponge hypothesis suggests a mechanism by which the polymers such as PEI containing protonatable moieties lead to chloride influx from the cytosol and subsequent osmosis into the endosome, resulting in endosomal swelling and lysis. Endosomal lysis allows the polymer and its cargo to be released into the cytosol [21].

Acid-sensitive liposomes have been extensively used to deliver macromolecular therapeutics agents. The first example of pH-sensitive liposomes was outlined by Yatvin et al. [22]. The mechanism of acid-induced fusion between liposomes composed of DOPE and palmitoylhomocysteine was further established by Connor et al. [23]. As outlined in the review by Simões et al. [24], three hypothetical mechanisms of cytosolic delivery from liposomes have been proposed: (1) Destabilization of pH-sensitive liposomes destabilizes the endosomal membrane possibly through pore formation, (2) destabilization of pH-sensitive liposomes allows cargo to diffuse through the endosomal membrane, and (3) liposomal membrane fusion with the endosomal membrane (illustrated in Figure 3.3-1). Several pH-sensitive lipids have been designed to promote endosome-to-cytosol transfer of macromolecules using liposomal systems. Fusogenic lipids such as oleic acid and cholesteryl hemisuccinate contain weak acids as head groups. These lipids, when incorporated into liposomes, induce pH-dependent fusion. Wang and Huang demonstrated the utility of oleic acid-containing pH-sensitive liposomes in mediating targeted delivery of transgenes to lymphoma tumors *in vivo* [25]. Other examples for weak acid-based pH-sensitive lipids include the titratable, double-chain amphiphiles 1,2-dipalmitoyl-sn-3-succinylglycerol (1,2-DPSG), 1,2-dioleoyl-sn-3-succinylglycerol (1,2-DOSG), and 1,3-dipalmitoylsuccinylglycerol (1,3-DPSG) developed by Collins et al. [26]. The fusogenicity of these lipids in the liposomal formulation is greatly enhanced by the incorporation of dioleoylphosphatidyl ethanolamine (DOPE), a neutral fusogenic lipid.

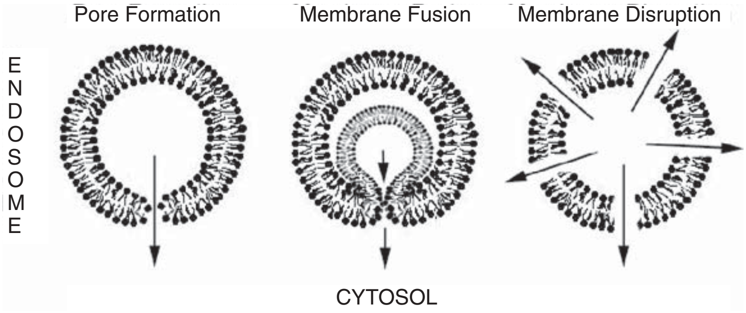

Figure 3.3-1. Mechanisms of endosome-to-cytosol transfer facilitated by various drug carriers.

The neutral dioleoyldimethylaminopropane (DODAP) free base tends to be fusogenic; however, protonation of the tertiary amino head group results in a bilayer-forming cationic lipid. It has been shown that interaction of the cationic lipid head group with anionic membrane-associated moieties such as proteoglycans results in a charge neutralization, which in turn, triggers the lamellar-to-hexagonal phase transition of such cationic lipid-based carriers. This nonbilayer phase transition is thought to promote extensive fusion between the liposomal formulation and the cellular membrane. Another example of weak base carriers is a series of amphiphilic imidazole-containing lipids. These lipids have been shown to efficiently promote the delivery of plasmid DNA to the cytoplasm [27]. As observed in the case of weak acid lipids, the fusogenic activity of the weak base lipids is potentiated by the presence of DOPE, a "helper" lipid that prefers the hexagonal phase above a temperature of 10°C.

Chen et al. synthesized a series of acyloxyalkyl imidazole lipids, with membrane-bound pKa values in the range of 5.0 to 5.5 [28]. It was expected that these molecules, once protonated in the acidic environment of the endosome, would become surface active and permeabilize the endosomal membrane. Eventually these lipids are degraded by cytosolic esterases into imidazole, formaldehyde, and the corresponding fatty acid. However, a serious limitation that precludes utilization of single-tailed, pH-sensitive detergents for the cytosolic delivery of macromolecules is their low limit of incorporation in stable liposomal formulations. Limited incorporation of detergent molecules resulted in a lack of liposomal collapse that leads to minimal endosomal membrane destabilization [29]. However, over-incorporation of such detergents destabilizes the liposomal membrane and would result in premature leakage of entrapped cargo. To address this issue, two Gemini surfactants or "bis-detergents" have been prepared by cross-linking the headgroups of single-tailed, tertiary amine detergents through oxyethylene (BD1) or acid-labile acetal (BD2) moieties [30]. The ability of BD2-containing liposomes to promote efficient cytosolic delivery of antisense oligonucleotides was confirmed by (1) their diffuse intracellular distribution observed in fluorescence micrographs, and (2) the upregulation of luciferase in an antisense functional assay. The low pH-responsive, bis-detergent constructs described herein are suitable for triggered release strategies targeted to acidic intracellular or interstitial environments.

3.3.2.2 Acid-Labile Linkers and Drug Carriers

Acid-labile linkers that are cleaved off in the endosomal milieu have been used in conjugating chemotherapeutic agents such as doxorubicin to targeting moieties such as folic acid, antibodies, and antibody fragments. Some common examples are acid-labile ketals, hydrazones, diorthoesters, and the *cis*-dicarboxylic acid linkers, which undergo intramolecular catalysis at low pH. Additionally, such moieties can also be conjugated to carrier molecules such as lipids to create an inactive pro-carrier. Hydrolysis of the pro-moiety at a low pH activates the carrier, which disrupts, destabilizes, or fuses with the endosomal membrane and subsequently promotes the release of entrapped molecules.

Recently, Murthy et al. have synthesized an acid-sensitive microgel material for the development of protein-based vaccines. The chemical design of these microgels is such that they degrade under the mildly acidic conditions found in the phago-

somes of antigen-presenting cells (APCs). The rapid cleavage of the microgels leads to phagosomal disruption through a colloid osmotic mechanism, releasing protein antigens into the APC cytoplasm for class I antigen presentation [31, 32]. Other examples of such acid-labile hydrogels include poly(orthoester) microspheres [33] and poly(ketal) nanoparticles [34] that undergo acid-catalyzed hydrolysis into low-molecular-weight hydrophilic compounds and release encapsulated therapeutics at an accelerated rate in acidic environments.

With respect to lipid-based drug carriers, an attractive approach for triggered release is to design cleavable surfactants with uncharged functional groups whose hydrolysis is catalyzed by acidic conditions. The chemical principles behind this approach have been described in an outstanding review published almost three decades ago [35]. For example, Boomer and Thompson reported several mono- and diplasmenyl lipids with an acid-sensitive vinyl ether linkage between the headgroup and one or both of the hydrocarbon side chains [36]. Upon exposure to low pH or photo-oxidation, the vinyl ether side chains are cleaved from the lipids, leading to structure defects in the bilayer and the release of liposomal contents. In another example, Guo and Szoka used a diorthoester bridge to link PEG to distearoylglycerol. This lipid efficiently stabilizes DOPE bilayer vesicles at a total lipid concentration as low as 10%. Release of the PEG by cleavage of the acid-labile diorthoester linker disrupts the lamellar organization and promotes the fusogenic lipid configuration of DOPE within the endosome. Subsequent fusion with the endosomal membrane resulted in cytoplasmic delivery of liposomal contents. These strategies have been reviewed extensively by Guo and Szoka [37, 38].

3.3.2.3 Redox/Enzyme-Triggered Drug Carriers

In addition to lower pH, the endosome also exhibits other characteristics that can be used in cytosolic delivery. The endosome houses many enzymes, including redox enzymes [9], and may exhibit a slightly reductive environment, although the latter portion of this statement currently remains a subject of controversy [10]. Using a listeriolysin O-protamine conjugate, the reducing potential of the endosome was exploited for plasmid DNA delivery into the cytosol [39]. The conjugate contained a redox-labile disulfide bond between the cysteine of listeriolysin O and the polycationic peptide protamine, which could be reduced in the reductive environment of the endosome. Upon disulfide cleavage, listeriolysin O exerted its endosomolytic activity, resulting in the cytosolic release of condensed DNA polyplexes.

Liposomes prepared from DOPE and a disulfide-containing cationic lipid showed a greater release of plasmid DNA than a non-disulfide-containing analog [40]. The disulfide bond of the lipid, 1-2-dioleoyl-sn-glycero-3-succinyl-2-hydroxyethyl disulfide (DOGSDSO), was shown to be cleaved in the reductive environment leading to the destabilization of the liposome-DNA complex (lipoplex) and increased transfection activity. A novel set of cationic lipids was designed to confer reduction-sensitivity for lipopolyamines [41]. These lipids contain a disulfide bond at different sites on the lipid backbone. Compared with nondegradable lipopolyamine analogs, increased transfection efficiency is observed when inserting the disulfide between one lipid chain and the rest of the molecule. However, loss or a substantial decrease in transfection activity occurs when the disulfide bridge is placed in the linker position between the polyamine and the lipid chains.

Chittimalla et al. have designed cationic thiol-based detergents [42]. Subsequent detergent polymerization by formation of intermolecular disulfide bonds within the condensed plasmid DNA leads to 32-nm-large neutral particles that promote efficient gene delivery.

Enzymatic cleavage of a synthetic peptide-lipid conjugate has been shown to trigger liposomal fusion to cellular membranes, thus allowing liposomal cargo to be distributed to the cytosol [43, 44]. The conjugate, formed from the covalent linkage of dioleoyl phosphatidylethanolamine (DOPE) with an elastase substrate N-acetyl-ala-ala-, having no intrinsic fusogenic activity, required cleavage by elastase or proteinase K and subsequent conversion to the fusogenic lipid DOPE. Only a few examples of enzymatic triggering have been described here although many enzymatic triggers have been studied. A few of these have explored the use of alkaline phosphatase [45], matrix metalloproteinases [46], and elastases [47].

3.3.2.4 Caveolae-Mediated Cytosolic Delivery

A variety of lipid-anchored membrane proteins are associated with caveolae that exist as a subdomain in a biochemically defined glycolipid raft. Not surprisingly, the intracellular trafficking of a given ligand is largely determined by what protein in caveolae they bind. It ranges from ultimate transcytosis as often found in endothelial cells, direct discharge to cytosol of folates, or endoplasmic reticulum and Golgi as in the case of simian virus 40 and cholera toxin, respectively [48–50]. The glycosylphosphatidylinositol (GPI)-anchored folate receptor-α (FR-α) internalizes and subsequently discharges 5-methyltetrahydrofolate and other folates directly to cytoplasm upon dissociation with FR-α in response to an acidic environment [48]. Although clustering of GPI-anchored proteins such as FR-α in lipid raft remains controversial [51], the current literature is rich in its application to cellular delivery of macromolecules and submicron drug carriers [52, 53]. Another unresolved issue is whether chemical modification of α-Glu of folate affects recognition of the conjugate by FR-α. A recent study reported no difference in liposomal delivery of antisense oligonucleotides when the surface was grafted with α- or γ-modified of folic acid [54].

3.3.2.5 Cell-Penetrating Peptides: HIV-TAT

The HIV TAT peptide is a short polybasic peptide sequence derived from the HIV-1 TAT protein, which plays a critical role in viral replication. The 11 amino acid TAT peptide is capable of penetrating cell membranes without causing membrane disruption. The TAT peptide was originally thought to enter cells directly at the plasma membrane via a nonsaturable, nonenergy-dependent mechanism [55, 56], possibly via transient formation of non-bilayer structures during the membrane penetration [57]. Recently, however, this picture has changed dramatically to a view that CPPs enter cells via saturable, energy-dependent processes involving endocytosis. Some early studies indicating nonendocytic uptake are now believed to reflect fixation artifacts [58]. Furthermore, cell-surface receptors for TAT protein chimeras were identified as being heparan sulfate proteoglycans [59, 60]. Additional studies showed that TAT and several other cationic CPPs clearly entered the cell by endocytosis, possibly via lipid raft [61, 62], and their release into the cytoplasm involves endosome acidification [58, 63–65].

3.3.3 DIRECT CYTOSOLIC DELIVERY ACROSS THE PLASMA MEMBRANE

Until recently, strategies for cytosolic delivery of macromolecules have largely been formulated by mimicking the cellular entry pathways of viruses and bacteria. Among these strategies, most have focused on promoting endosomal escape of macromolecules into the cytosol exploiting features such as acidic pH and redox/enzyme activity within endocytic vesicles. Nevertheless, simpler methods to deliver large macromolecules directly across the plasma membrane, while bypassing the degradative endocytic pathway, have been pursued. In particular, the seminal discoveries that peptides derived from glycoproteins embedded in the lipid envelope of viruses such as HIV and Herpes virus as well as those derived from the homeodomain of certain transcription factors can directly translocate across the plasma membrane of mammalian cells have opened up new avenues in macromolecular drug delivery. In general, these "cell-penetrating peptides (CPPs)" are approximately 30-amino-acid-long amphipathic peptides with a net positive charge [66]. The most prominent examples of CPPs are the HIV-TAT, discussed in the previous section, penetratins, and synthetic peptides derived thereof. Less-studied examples such as the peptides derived from HIV gp41 and the Herpes VP22 are also discussed (Table 3.3-1).

TABLE 3.3-1. Examples of Peptide Sequences of Common Cell-Penetrating Peptides

HIV-TAT	H_2N-**GRKKRRQRRRPPQ**-$CONH_2$
PENETRATIN	H_2N-**RQIKIWFQNRRMKWKK**-$CONH_2$
TRANSPORTAN	H_2N-**GWTLNSAGYLLGKINLKALAALAKISIL**-$CONH_2$
SN50	H_2N-**AAVALLPAVLLALLAP**-$CONH_2$

The main application of CPPs is the attachment of biologically active cargo for translocation into cells. Conjugating cargo to CPP can be achieved through several means. When the cargo is a peptide or protein, CPP and cargo are most often synthesized or expressed in tandem as a fusion protein. Alternatively, a suitable amino acid side-chain or bifunctional spacer molecule can be used to couple cargo to CPPs through maleimide-thiol, disulfide, or amine-carboxylate chemistry. Attachment of cargo to CPP can also be achieved via noncovalent bonds, employing for instance the interaction between streptavidin and a biotinylated CPP conjugate. When chemically conjugated, TAT has been shown to enhance intracellular delivery of oligonucleotides [67–71], peptides and proteins [72, 73], and particulates [74, 75]. The strategy has met with moderate success *in vivo* [76–79]. Several strategies involving target proteins fused to the TAT peptide have also been described [80, 81]. The technology requires the synthesis of a fusion protein, linking the TAT transduction domain to the molecule of interest using a bacterial expression vector, followed by the purification of this fusion protein under either soluble or denaturing conditions. The original 11-residue TAT sequence (47–57) has been extensively modified to improved versions of TAT [82], poly-arginine peptides [83, 84], and guanidinium-rich peptoids [84].

3.3.3.1 Cell-Penetrating Peptides: Penetratin and Other Peptides

Penetratins are a class of CPPs derived from transcription factor proteins of Antennapedia (a *Drosophila* homeoprotein). Using site-directed mutagenesis, it was discovered that the third helix (amino acids 43–58) of the latter homeodomain was necessary and sufficient for translocation. Structure–function studies of penetratin yielded several active and inactive analogs that allowed formulation of the inverted micelle internalization model. The cellular internalization of penetratins occurs at 37°C and 4°C through a nonsaturable mechanism. The demonstration that retro-inverso penetratin analogs and similar peptides derived from other homeodomains are capable of membrane translocation suggests that the number of member peptides comprising the penetratin family is high.

Transportans are 27-amino-acid-long chimeric peptides designed and synthesized from other unrelated peptides. The first 13 amino acids are derived from the highly conserved amino-terminal part of galanin, whereas the 14-residue C-terminus is derived from the wasp venom peptide toxin, mastoparan. Although the N-terminus portion is the smallest highly active galanin receptor ligand with agonist properties, the C-terminus end is thought to penetrate the cell membrane by creating transient pores by translocating into the inner leaflet of the membrane bilayer. Applications of transportans have been similar to that of HIV-TAT and penetratins and have been discussed in detail elsewhere. Morris et al. designed a synthetic CPP that contains a hydrophobic domain derived from the HIV fusion protein, gp41, and a polycationic sequence derived from the nuclear localization sequence of the SV40 T-antigen [85]. The peptide vector exhibits a high affinity for single- and double-stranded DNA in the nanomolar range and has been used for the nuclear delivery of oligonucleotides, siRNA, and plasmid DNA. Although unclear, the peptide vector seems to facilitate direct cytosolic and nuclear delivery of cargo through nonendocytic means.

Elliott and O'Hare demonstrated that the Herpes simplex virus protein VP22 exhibits the remarkable property of intercellular trafficking, whereby the protein spreads from the cell in which it is synthesized to many surrounding cells [86]. This function of VP22 has been exploited to construct fusion proteins similar to aforementioned strategies that retain their ability to spread between cells and accumulate in recipient cell nuclei. The extreme C-terminus (residues 267–301) of VP22 is thought to be required for membrane translocation. However, further studies by Aints et al. indicate that although this region facilitates VP22 transport, a core region in the protein (residues 81–195) also contributes to transport activity [87]. VP22 has effectively delivered proteins such as GFP, p53, and the SV40 T antigen in both actively dividing and terminally differentiated cell lines. It has been successfully employed to enhance the effectiveness of thymidine kinase and cytosine deamidase suicide gene therapy systems for cancer therapy both *in vitro* and *in vivo*. VP22 fusion proteins have also been successful in enhancing the efficacy of lentivirus and adenovirus-based gene therapy systems. Additionally, when combined with small oligonucleotides, VP22 forms spherical particles, named Vectosomes, that are taken up by an energy-dependent process when applied to cells in culture.

Hawiger has developed CPPs derived from the membrane-translocating hydrophobic sequence of the h-region of the signal peptide sequence of K-FGF [88].

These alanine and leucine-rich peptides adopt a predominantly alpha-helical conformation in solution. A particularly striking characteristic of these CPPs (SN50) is the presence of a kink in the center of the alpha-helix due to a single proline, which is thought to play a key role in the membrane translocating activity of these peptides. Several studies testing the ability of these CPPs to carry functional cargo have been applied to control signal transduction-dependent subcellular traffic of transcription factors such as NF kappa-B mediating the cellular responses to different agonists. More recently, the authors have used the SN50 peptide sequence for intracellular protein therapy with SOCS3 to inhibit inflammation and apopotosis induced by bacterial enterotoxins [89].

3.3.3.2 Molecular Umbrellas

A conventional strategy to enhance transbilayer transport of several drugs, at least in the case of small molecules, is to simply modify the lipophilicity of the molecule by chemical conjugation to hydrophobic species such as fatty acids or cholesterol. However, such strategies seem merely to facilitate the adsorptive pinocytosis of macromolecules owing to their highly polar nature. Steven Regen et al. have extended this principle beyond simply altering the hydrophilic/hydrophobic balance of macromolecules. Their strategy hinges on an "umbrella" mechanism involving chemical conjugates that adopt a shielded conformation to traverse the plasma membrane (Illustrated in Figure 3.3-2, [90]).

Molecular umbrellas are a unique class of amphiphiles that are capable of shielding an attached agent from an incompatible environment. Typically, such molecules are composed of a central scaffold that contains two or more facially amphiphilic units. When a hydrophilic agent is attached to an umbrella molecule, contact with water favors an exposed conformation such that intramolecular hydrophobic interactions are maximized. Alternatively, when immersed in a hydrophobic environment, such as the lipid bilayer, the molecular umbrella can shield the agent by providing a hydrophobic exterior. Recent mechanistic studies have provided strong evidence that facial amphiphilicity plays a major role in umbrella transport across lipid bilayers. The fact that facial amphiphilicity is more important than hydrophobic/hydrophilic balance in promoting transbilayer transport lends strong support for

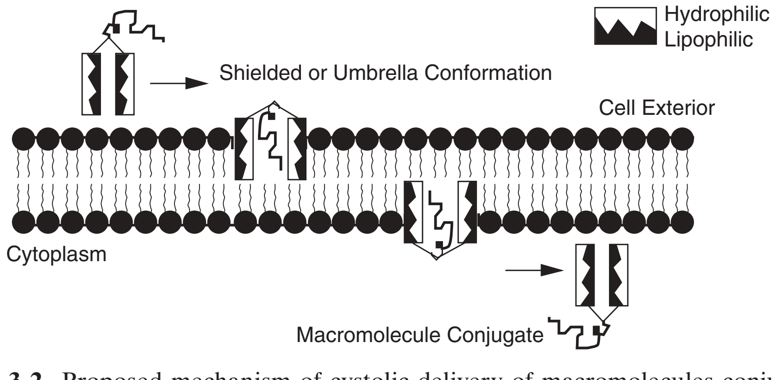

Figure 3.3-2. Proposed mechanism of cystolic delivery of macromolecules conjugated to molecular umbrellas.

an umbrella mechanism. In essence, the permeation pathway involves monolayer insertion of a shielded conformer, transbilayer diffusion, and entry to the opposite membrane/water interface. These molecular umbrellas were demonstrated to promote transport and release of small peptides by using a detachable handle based on disulfide cleavage. More recently, a series of molecular umbrellas derived from cholic acid, deoxycholic acid, spermidine, lysine, and cleavable disulfide linkages were found capable of transporting an attached 16-mer oligonucleotide across liposomal membranes. The ability of these novel agents in promoting the membrane translocation of macromolecules in a cellular setting remains to be seen [91].

3.3.4 ASSAYS FOR MONITORING CYTOSOLIC DELIVERY

In principle, the drug carrier or cargo molecules or both could be labeled with a variety of different radionuclides such as [^{125}I] or [^{3}H] for quantitative assessment. However, the disadvantage associated with such assays is the need for separating the cytosolic fraction from organelles such as endosomes, lysosomes, and nuclei using differential centrifugation techniques. Zaro and Shen have developed a novel method to quantitate the membrane transduction efficiency of CPPs and other drug carriers [92]. In essence, the amount of oligopeptide located in the cytoplasmic compartment was separated from the amount located in the intracellular vesicles using size exclusion chromatography. This separation allowed for the measurement of the membrane transduction efficiency of various [^{125}I]-labeled oligopeptides.

Most assays to determine the efficiency of cellular uptake and cytosolic delivery of macromolecules have involved the use of fluorescence microscopy or flow cytometry techniques. However, a major drawback associated with such qualitative fluorescence-based assays is their propensity for generating false-positives. For example, in the abundant literature dealing with CPPs, optimistic reviews highlighting their promising properties coexist with articles questioning their actual efficacy. The tight binding of most CPPs to negatively charged cell surfaces is responsible for microscopy misinterpretations. Methods such as methanol fixation of cells before microscopic observations have been shown to redistribute CPPs. Thus, the experimental assessment of the cytosolic delivery of proteins and other macromolecules is hindered by these artifacts. In fact such artifacts, which affect conventional as well as confocal microscopy analyses, has led to the false conclusion that CPPs, such as TAT and Penetratin, enter cells through an endocytosis-independent fashion [58, 93]. Recent studies suggest that the interaction of HIV-TAT with the cell surface leads to internalization of HIV-TAT fusion proteins by lipid raft-dependent macropinocytosis.

Owing to aforementioned issues, assays that reflect the functional activity of the cargo rather than the carrier have been developed. These assays can broadly be categorized on the basis of protein-based drugs and nucleic acid therapeutics. Prerequisite conditions for presentation of antigenic peptides through the MHC class I pathway are endosomal escape, followed by ubiquitin conjugation in the cytosol, which in turn targets the protein for proteasomal degradation. Conventional antigen presentation assays based on activation of cytotoxic T lymphocytes by monitoring cytokine levels and [^{51}Cr] release from target cells have been described elsewhere. Loison et al. have devised an ubiquitin-based assay for monitoring the cytosolic

delivery using CPPs [94]. The authors developed a stringent enzymatic assay based on the processing of a CPP-Ubiquitin-Cargo fusion protein by exclusively cytosolic deubiquitinating enzymes. Based on this strategy, insertion of a ubiquitin moiety between the CPP and the protein cargo serves as a stringent test of cytosolic delivery by ensuring the cytosolic release of the cargo, followed by its proper folding and localization, which is required for interaction with intracellular targets.

Another relatively simple approach to assess cytosolic delivery is to monitor direct enzymatic activity of the protein cargo, such as β-galactosidase or horse radish peroxidase. However, as such enzyme activity could be recovered from within endosomes after fixation and staining, it is not possible to quantitate the cytosolic fraction exclusively. To address this question, a functional assay using a conjugate of TAT-RNase A was tested for its ability to inhibit protein synthesis through the nonspecific degradation of cellular RNA. In this model, if TAT-RNase A were entering the cell and remaining within endosomes, there should be no effect on protein synthesis. However, cytosolic entry of TAT-RNase A was found to be sufficient to decrease cellular protein synthesis as monitored by [^{35}S]-methionine incorporation. Another functional assay involved the use of TAT-Cre-Recombinase to mediate recombination of a *lox*P-STOP-*lox*P enhanced green fluorescent protein (EGFP) reporter gene in live mouse reporter T cells (tex.loxP.EG) as a measure of cellular uptake [81]. This system requires that exogenous TAT-Cre protein enter the cytosol, translocate to the nucleus, and excise the transcriptional STOP DNA seg-ment in live cells in a nontoxic fashion before scoring positive for EGFP expression.

Nucleic acid-based therapeutics such as antisense oligonucleotides, siRNA, and plasmid DNA act by interaction with translational or transcriptional protein machinery to downregulate a specific protein or promote transgene expression. In contrast to protein cargo, the interpretation and quantitation of cytosolic delivery of RNA/DNA-based therapeutics is relatively straightforward. Within this framework, reporter proteins such as luciferase and EGFP have been commonly used. Among several functional assays, the upregulation of reporter proteins by correction of aberrant splicing using antisense oligomers is notable [95]. This assay has recently been extended into an *in vivo* mouse model. In this model, the expressed gene (*EGFP-654*) encoding enhanced green fluorescence protein is interrupted by an aberrantly spliced mutated intron of the human β-globin gene. Aberrant splicing of this intron prevents expression of EGFP in all tissues. However, cytosolic entry of the splice site-targeted antisense oligomer restores corrective splicing and results in upregulation of EGFP in several tissues and organs.

4.1.1 INTRODUCTION TO BIOPROCESSING

In general the manufacturing methods for proteins and plasmid DNA require a cellular medium to either express a protein or replicate genetic material, which is later harvested and separated from undesirable cellular material. The type of cell culture will play a large role in the efficiencies of macromolecular production as well as in the separation process. Often forgotten are the manufacturing steps that bridge the raw purified product and that which is delivered. Lyophilization, encapsulation, delivery, and formulation steps suffer many of the same issues as those in the initial growth and harvesting steps. In the following sections, we briefly describe the initial manufacturing steps involved in the production of therapeutic proteins and plasmid DNA so that later sections specific manufacturing issues can be placed in context. However, it is in these later sections we will draw connections to the later manufacturing stages.

4.1.1.1 General Method for Manufacturing Therapeutic Proteins

The production of therapeutic protein starts with the design of a recombinant DNA that is typically transfected into mammalian cells, *Escherichia coli*, or yeast, although some transgenic plants and animals are being employed. Conditions, especially in the medium, that elicit the excretion of the desired proteins into extracellular medium are typically preferred over harvesting through cell disruption because of the reduction in contaminants and subsequent purification steps required. The recovery of the product in active form is complicated by protein aggregation that can be promoted by separation and purification processes. It should be recognized that the medium that generated the best protein extrusion may now hinder recovery because of high viscosity or a tendency to promote colloids due to the elevated protein concentrations. The isolation stage normally involves high-pressure homogenization, bead milling, centrifugation, filtration, precipitation, and/or ultrafilration. This stage is followed by a purification stage involving chromatographic sequence (i.e., polishing, desalting, buffer exchange, ion exchange, and reverse phase) that balances yield and purity. An in-depth discussion of all unit-based application can be found in Ref. 1.

4.1.1.2 General Methods for Manufacturing Plasmid DNA

The production of plasmid DNA begins with the replication of the desired therapeutic gene by bacterial cells, most often *E. coli* [2]. The cells are allowed to grow in a nutritious broth before they are harvested, typically by centrifugation. In a process called cell lysis, the harvested cells are broken open either mechanically (e.g., high-pressure homogenizer), enzymatically, or chemically (e.g., alkaline lysis). During this process the contents of the cells, including plasmid and genomic DNA, are most susceptible to shearing forces as they are no longer protected by the bacterial membrane. There are several ways of removing and purifying the plasmid DNA from the rest of the cell debris. These ways include centrifugation, filtration, and chromatography methods, which are briefly reviewed by Durland and Eastman [3].

4.1.2 REVIEW OF MOLECULAR STRUCTURE

Like all polymers, proteins and DNA are composed of a sequence of repeating units that interact at various levels to produce the active structure. Although the primary structure of DNA does largely determine its physical and biological properties, that of proteins is of minimal use in determining the desired active structure. This section is not intended to replace a biochemistry textbook, but it provides the basic information necessary to understand how the molecular structure of proteins and plasmid DNA differ, and how this impacts macromolecular stability in a general sense.

4.1.2.1 Comparison of Protein and DNA Primary Structure

Proteins, peptides, and polypeptides are single-stranded polymer chains composed of repeating amino acids (20 different amino acids are available) and only differ in the number of amino acids that comprise the polymer chain. Although the definitions of these terms are not strictly defined, peptides typically have less than 50 amino acids, whereas polypeptides possess up to 100 amino acids, and proteins generally have more than 100 amino acids covalently linked (through "peptide" bonds) into a polymer chain. Analogous terms for small polymers of nucleic acids, "oligonucleotide" and "polynucleotide," generally refer to chains of <50 and >50 nucleotides (adenosine, guanosine, cytosine, or thymidine), respectively. There is no term for nucleic acids that is analogous to "protein," but long strands of nucleic acids are typically produced as a plasmid, and they are generally >3000 nucleic acids in length. A critical difference between proteins and plasmid DNA is that proteins are a single polymer chain, whereas plasmid DNA consists of two strands that are associated in the classic double helix. Although DNA used for antisense therapy is typically single stranded, thereby designed to associate with a specific sequence to exert a therapeutic effect, these molecules are typically 10–30 nucleotides in length (oligonucleotides) and are chemically synthesized instead of being produced in bacteria as described above. Although the chemical synthesis of oligonucleotides presents its own set of purification issues that are reviewed by Sanghvi and Schulte [4], our discussion will focus on issues involved with the bioprocessing of plasmid DNA.

Simply based on the number of atoms participating in the primary structure of these biopolymers, proteins have a smaller hydrodynamic diameter (<30 nm), whereas typical plasmid DNA molecules range from 100 to 400 nm. As a result, proteins are less susceptible to mechanical forces, especially hydrodynamic forces. This resistance is simply due to a size range that is well below the continuum limit of the fluid. In other words, when particle sizes are well below 100 nm (Figure 4.1-1) in aqueous solutions, they "slip" between water molecules rather than having a drag force applied continuously over the particle surface.

4.1.2.2 Comparison of Protein and DNA Higher Order Structure

Unlike most polymers, these biopolymers have extraordinary secondary and tertiary structures that can dramatically affect therapeutic efficacy. For example, proteins form complex geometries based on hydrophobic interactions and hydrogen

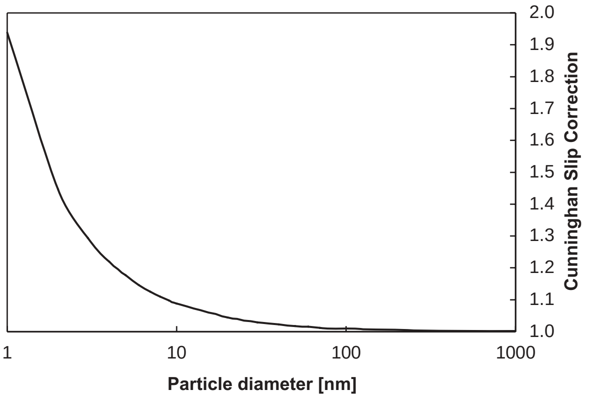

Figure 4.1-1. Cunningham slip correction vs. particle diameter for water fluid flow.

bonding, which results in well-defined structures, e.g., beta sheet and alpha helix. Because these structures rely on relatively weak bonding interactions (i.e., noncovalent), protein molecules are acutely sensitive to changes in pH and hydrophobic/hydrophilic interfaces. In contrast, plasmid DNA is a double-stranded helix that is produced as a circular form. In addition, this circular form is coiled in a direction opposite that of the double helix, resulting in “negative supercoils” that create torsional stress in the supercoiled form of the molecule. The added stress due to supercoiling is stored in the plasmid and cannot be relieved unless a break occurs in the covalent bonds comprising the phosphate backbone. However, the cleavage of a single covalent bond in the backbone of either strand composing the double helix results in the release of this torsional stress and conversion of the supercoiled form to the relaxed, “open circle” form. Another cleavage in the phosphate backbone of the opposite strand that is in the same vicinity (within a few nucleotides) of the first break will cause the circular integrity to be broken, resulting in a linear form of the plasmid. Because the supercoiled form requires an intact backbone in both DNA strands, supercoil content (the percentage of plasmids that are in the supercoiled form) is used as a measure of quality for a plasmid preparation. Typically, plasmid preparations used in clinical trials have supercoil contents of >90%. Not surprisingly, it is critical that stresses during bioprocessing be low enough to ensure that the integrity of the phosphate backbone is retained so that preparations with sufficiently high supercoil contents are produced.

4.1.3 MANUFACTURING CONCERNS

Basic manufacturing concerns fall into three categories: those associated with chemical interaction, mechanical phenomena, or thermodynamic energy states. In the following sections, we attempt to provide a general overview of the most common problems as well as the most commonly perceived problems: whether real or imaginary. A clear understanding of the source of degradation during a specific manufacturing process is essential to developing successful mitigation strategies. Numerous mitigation techniques have been described in literature, but it should be

recognized that the best option is dependent on the ultimate form in which the molecule will be administered, e.g., free or in a delivery system.

4.1.3.1 pH Sensitivity

Extreme pH has been shown to have a role in the break down of macromolecular structure in aqueous solution via hydrolysis [5–7] and aggregation. For example, DNA can disintegrate by depurination reactions resulting in the loss of a purine base and the creation of apurinic (AP) sites. This absence of a base weakens the molecular chain, thereby leading to an increased susceptibility to hydrolytic attack [6]. The destabilized DNA can then undergo beta-elimination of a phosphodiester bond in the backbone, resulting in strand breaks and loss of the supercoiled form. These reactions can be accelerated if pH levels fall below 7.5 or rise above 9.0 [8].

In contrast, proteins will not denature in the same way when exposed to varying pH solutions. Therapeutic proteins are often only stable over a narrow pH range; outside these limits, the aggregation rate is strongly influenced by pH. A solution pH governs the total charge on a molecule; thus, it can affect intra- and intermolecular interactions. Increasing the acidity or alkalinity of the solution beyond the stable range will highly charge nonspecific groups within the protein generating strong repulsive forces, thus destabilizing the protein [9].

pH sensitivity is well known by process engineers, and solution pH is usually carefully controlled, but manufacturing steps that include a gas–liquid interface can unintentionally lower pH if solutions are not properly buffered. The diffusion of carbon dioxide into the aqueous solution could be facilitated by the use of a driving gas that produces a large gas–liquid interface across which substantial gas exchange can occur. Localized nonequilibrium supersaturation of carbon dioxide can lead to large transient changes in pH because carbon dioxide in water can form carbonic acid that can deprotonate and acidify the solution [10].

$$CO_2 + H_2O \rightarrow H_2CO_3$$

$$H_2CO_3 \rightarrow H^+ + HCO_3^-$$

4.1.3.2 Metal Catalyzed and Enzymatic Degradation

Trace amounts of reduced transition metal ions such as iron and copper are known to generate hydroxyl radicals resulting in oxidized nucleotide bases and strand breaks by means of Fenton-type reactions [11–15]. Diethylenetriaminepentaacetic acid (DTPA) and ethylenediamine tetraacetic acid (EDTA) are compounds that chelate metal ions present in solution or bound to macromolecules. These chelators have also been shown to inhibit DNA degradation via DNase by binding various divalent cations (e.g., Mg^{2+}) necessary for enzymatic activity [16].

4.1.3.3 Hydrodynamic Degradation

Observations of hydrodynamic shear-induced degradation of long polymer molecules first appeared in the literature approximately 60 years ago when Frenkel [17]

mathematically demonstrated that hydrodynamic forces along a long polymer molecule could be sufficient to break covalent bonds. Early experimental investigations into the degradation of long linear DNA molecules blamed hydrodynamic shear forces for the observed fragmentation [18, 19]. These studies varied shear rates through needles and measured degradation through sedimentation rates. This technique did not allow for the clear distinction between molecular scission and structural changes, but these early experiments demonstrated the sensitivity of DNA to hydrodynamic shear stress encountered during stirring and pipetting. But as experimental techniques evolved, it become clear that the shear *rate* instead of the shear *force* was the dominant contributor. In their classic paper, Bowman and Davidson [20] provided the groundwork for relating the probability of fracture to the strain rate. These authors realized that the experimentally measured intact DNA concentration divided by the original concentration represented the total probability ($\langle P \rangle$); an integrated average over each radial position depending on the tube radius (R), volumetric flow rate (Q), tube length (l), and rate constant (k), which depends on strain rate (G). A complete review of the classic theory is available in Lengsfeld and Anchordoquy [21]:

$$\langle P \rangle = \frac{2\pi l}{Q}\int_0^R krdr \tag{4.1-1}$$

When even more conditions (i.e., length and flexibility of the molecule, strain rates, and shear forces) where explored, it became clear that the original classic theory needed modification to be applicable to bioprocessing. Recent work indicates that the degradation of very large biopolymers is similar to cell fragmentation, which has been linked to unsteady flow and turbulent intensity [22, 23]. When energy is transferred to a fluid, some is imparted to the motion of the bulk in a downstream direction, whereas some is consumed by turbulent mixing. This energy is transmitted from eddies on the order of the characteristic length through a cascade of sizes that terminate at the Kolmogorov length scale. At this length scale, energy is dissipated via viscosity.

Several studies investigating the dynamics of individual polymer molecules in flow demonstrated the transition of polymers in their natural coiled state to a stretched configuration in extensional flows [24–27]. Investigations that focus on simple shearing flow have demonstrated that the tumbling of the molecules prevents the elongation of the molecule [27–29]. In these cases, simple shear flow is defined as flow in which the strain rate is equal to the magnitude of the vorticity [28]. Random flows, however, have demonstrated that polymer molecules such as DNA can be effectively stretched [30–32]. In these cases, where the viscous scale of the flow exceeds the length of the polymer, constant strain is applied locally by the turbulent flow [32].

Theoretical models suggest that the transition from a coil-stretch transition within random flows depends on the principle Lyapunov exponent λ1 and the longest relaxation time for the molecule τ_R. To stretch the molecules, $\lambda_1\tau_R$ must be >1 [31, 32]. The Lyapunov exponent can be approximated by taking the fluctuating velocity u', divided by the characteristic length scale, which in turbulence, is determined by the eddies at the viscous scale; i.e., $\lambda = u'/\eta$ [31].

Yim and Shamlou [22] provide a comprehensive list of energy dissipation rates in each unit process used in the manufacture of biomolecules (Table 4.1-1). Worden [23] showed that degradation commences when the size of this small-scale turbulent structure becomes equal to or less than the molecule's hydrodynamic diameter (Figure 4.1-2). The scale of these smallest eddies η can be calculated based on the energy dissipation rate ε and the diffusivity ν using the relationship derived by Kolmogorov in 1941 [33]:

$$\eta = \left(\frac{\nu^3}{\varepsilon}\right)^{1/4} \tag{4.1-2}$$

Estimating the size of the smallest length scale is relatively simple. One could use computational fluid dynamic modeling techniques or estimate them based on the power input to the system (head loss) and the mass of the fluid being powered. For example, in pipe flow, the energy dissipation rate is a function of the total head loss in the flow h_{lt}, the volumetric flow rate Q, the density of the solution ρ, and the mass of the solution m, which in this case is the mass of fluid contained within the pipe [Equation (4.1-3)]

TABLE 4.1-1. Energy Dissipation Rate Estimates by Yim and Shamlou for Common Bioprocessing Equipment [22]

System	Energy Dissipation Rates [W kg^{-1}]
Homogenizer	10^7–10^9
Liquid whistle	10^7
Centrifuge	10^6–10^7
Collid mills	10^5
Pumps, jets	10^3–10^5
Agitated vessels	10^0–10^2
Static mixers	10^0–10^1
Bubble columns	<10^1

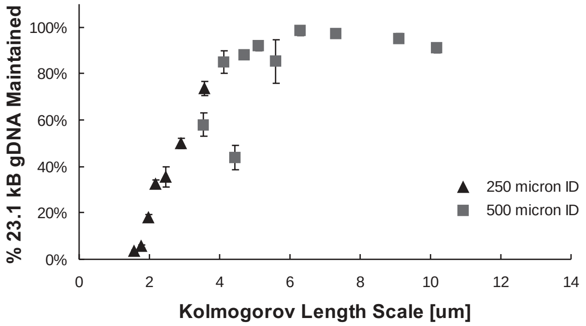

Figure 4.1-2. Degradation behavior of 23.1-kb genomic DNA during simple pipe flow with an initial contraction. Kolmogorov length scales were varied through changes in contraction ratio (i.e., pipe diameter) and pressure drop.

$$\varepsilon = \frac{h_{lt} Q \rho}{m} \tag{4.1-3}$$

Note that to create length scales lower than those of proteins in water requires energy inputs of 1012 W/kg, which is well above that achieved in bioprocessing. Thus, hydrodynamic degradation is only an issue in the production of large macromolecules, e.g., plasmid DNA.

4.1.3.4 Cavitation

A phenomena present in most pumping systems, but until recently ignored by process engineers is the impact of cavitation on macromolecular stability. For example, the pressure waves induced by the piezoelectric element in an ultrasonic nebulizer have compressive crests and tensile troughs (Figure 4.1-3). If sufficient tensile stress is applied at the fluid during the low-pressure cycle, a void of vapor will be formed. Dissolved gases can diffuse to this surface causing the bubble to grow. In stable cavitaion, the bubble oscillates in size about a mean diameter with the passing of the pressure waves. However, in transient cavitation, once the bubble has reached a critical size, the compressive pressure at the crest is sufficient to cause implosion. The bubble collapse releases significant energy in the form of a shock exhibiting high temperatures and pressures, which can generate free radicals.

The factors influencing cavitation are the solution's viscosity, surface tension, vapor pressure, and the presence of contaminants. In addition, the applied forcing frequency and amplitude can contribute to the efficiency of cavitation.

Manufacturing engineers can easily track transient cavitation using a well-established method. When water molecules are exposed to a shock wave (intense temperature and pressures), it becomes ionized into hydrogen and hydroxyl radicals, and two hydroxyl radicals can combine to form hydrogen peroxide. If potassium iodide is present in the solution, the peroxide will react and form iodide and potassium hydroxide. If the solution contains excess potassium iodide, the iodide will form triiodide, which can be measured spectroscopically using ultraviolet absorption at 350 nm. This is essential for plasmid DNA systems where we have determined that the DNA molecule serves as a nucleation site for cavitation. Lentz et al. [34] observed a reduction in nucleation efficiency with size, suggesting that proteins are too small (<30 nm) to nucleate cavitation:

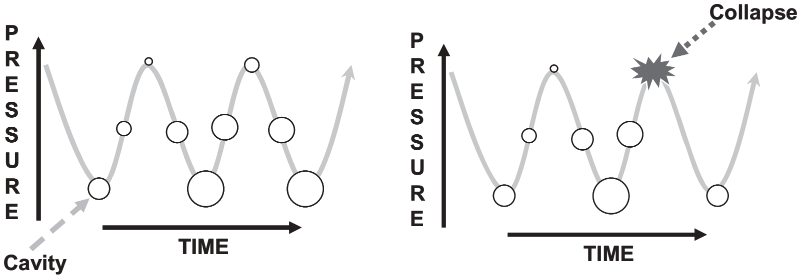

Figure 4.1-3. Schematic for the evolution of cavitation in (a) stable and (b) transient processes.

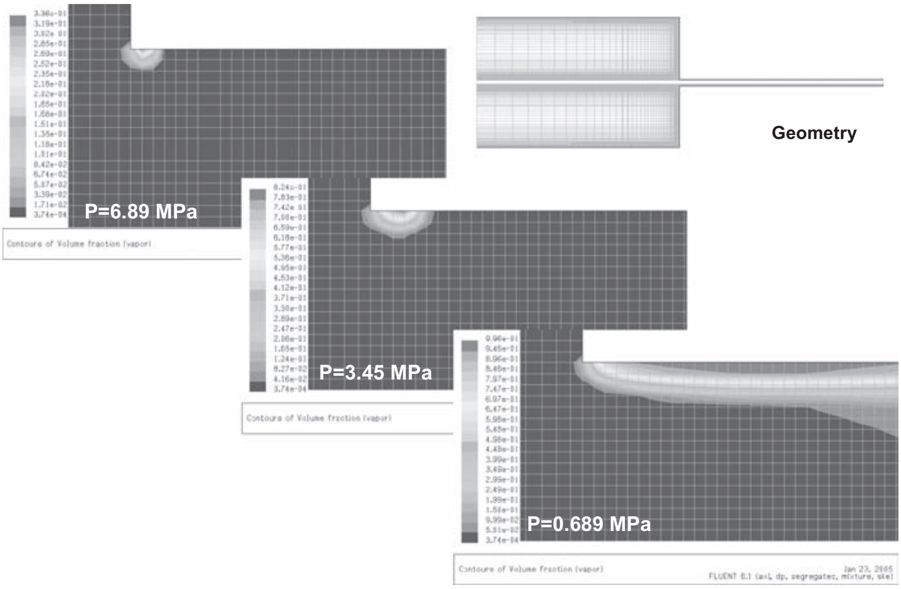

Figure 4.1-4. Computational fluid dynamics simulation of vapor fraction formation from a tube contraction as a function of tube length (diameter = 500 µm, pressure drop = 3.45 MPa). Red areas indicate 100% vapor regions within the pipe. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_tech_med/pharmaceutical_biotech/.)

$$\mathrm{H-O-H} \xrightarrow{\text{Cavitaton}} \mathrm{H^{\bullet} + H^{\bullet}}$$
$$\mathrm{2OH^{\bullet}} \longrightarrow \mathrm{H_2O_2}$$
$$\mathrm{KI + H_2O_2} \longrightarrow \mathrm{I_2 + 2KOH}$$
$$\mathrm{I_2} \xrightarrow{\text{Excess KI}} \mathrm{I_3^{\bullet}}$$

However, unlike DNA, proteins will degrade at the bubble interface. Therefore, modeling stable cavitation may be important in the design phase of protein bioprocessing systems. Figure 4.1-4 demonstrates this process using a commercial computational fluid dynamics (CFD) package to observe the formation of vapor phases in low-pressure regions around a tube contraction. As anticipated, the volume of vapor formed increases with decreasing tube length.

4.1.3.5 Surface Interaction

Gas–liquid interfaces are problematic when processing macromolecules [35, 36]. Proteins, due to their amphipathic nature, undergo conformational changes by adsorbing to the gas–liquid interface [36, 37]. The Gibbs free energy available at the interface allows the protein to rearrange such that hydrophilic components remain in solution while hydrophobic moieties associate with the gas phase. The addition of mild shear stresses can expedite this unfolding process. It was Maa and Hsu [37] who clearly showed the correlation between protein denaturation and surface-to-volume ratio under hydrodynamic shear conditions.

In addition, some research has hypothesized that an attack by molecular oxygen could accelerate the degradation rates of DNA [38]. For example, DNA bases and sugars would be oxidized, resulting in base alterations or strand breaks [5, 39]. However, the investigations by Lentz et al. [40] into the aerosolization of genetic therapeutics showed not evidence of this effect. Although proteins act as surface-active agents and diffuse to hydrophilic–hydrophobic interfaces, DNA is not surface active and remains relatively homogenous throughout the bulk of the fluid (Figure 4.1-5). As a result, oxidative attack is controlled by diffusion and solubility limits in aqueous solutions.

It is important to note that these molecules are highly charged and may preferentially diffuse to, or away from, the electric double layer formed at the interface of a metal surface and water. Adsorption to solid surfaces is controlled by electrostatic interaction, dispersion, hydration state, and structural rearrangement because the molecule must be transported from the bulk to the surface, attach, and then spread (complete review in Ref. 41). For example, in rigid proteins (e.g., those in poor solvents), the surface energy increases necessary to spread along the surface must be overcome. Flexible proteins (e.g., those in good solvents) will spread more readily. Most proteins are relatively stable in solution when processed under appropriate buffer conditions. However, at high concentrations, proteins are more likely to adhere to solid surfaces, especially glass and plastics.

What can be done to inhibit molecular adsorption to solid surfaces? Several techniques exist for the protection against surface-induced damage during fermentation, purification, freeze-drying, shipping, and storage. Surfactants and osmolytes (e.g., small organic solutes like sugars, methylamines, and amino acids) all have demonstrated protection against protein aggregation. Surfactants can enhance

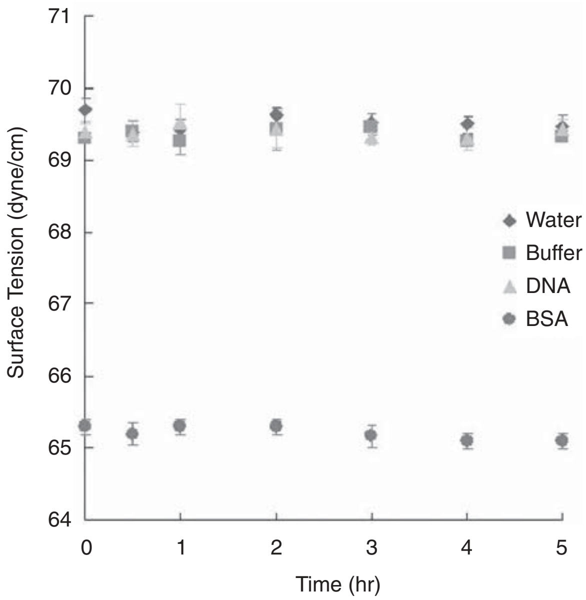

Figure 4.1-5. Magnitude of surface tension as a function of buffer, DNA, and protein (BSA) concentration [40].

protein stability in four ways by competing with proteins for adsorption sites on surfaces, binding to hydrophobic regions inhibiting intermolecular interactions, increasing the free energy of the unfolding pathway, and acting as a simple chaperone [42]. On the other hand, osmolytes, such as sucrose, are preferentially excluded from the protein surface, thereby increasing the potential energy and subsequently compacting the protein [43, 44]. Instead of manipulating the solution formulation, one can also alter the free energy of the surface. Coating the surfaces with materials that are not porous (i.e., large surface area) or those that are more hydrophilic will reduce adhesion. Exposure to gamma radiation or pulsed plasma [45] can alter the hydrophilic/hydrophobic state of a polymer surface by changing the functionalization of the surface molecules. Other groups have demonstrated that using polyDuramid or poly-N-hydroxyethacrylamid (PHEA) inhibits adhesion, whereas others in the microfluidic industry use polyethylene glycol (PEG) (plastics evaluation in Ref. 46).

4.1.3.6 Freeze–Thaw Cycling

The formation of discrete ice crystals during freezing causes boundaries to form between different crystal orientations. These boundaries have high surface energies that are known to contribute to fragmentation. As crystal size decreases, the probability that protein or DNA molecules will span one of these high-energy interfaces increases. When storing the therapeutic (plasmid DNA or protein) before use in secondary processing, it is essential to consider the freezing rate because high rates lead to smaller crystal sizes. These small differences in crystal morphology can cause significant batch-to-batch variability.

Embedding a macromolecular therapeutic in a highly crystalline polymer may experience a similar decrease in activity with decreasing particle size. Control over particle size during product formation may therefore be extremely important during fabrication steps.

4.1.4 EXAMPLE PROCESS—ATOMIZATION

Many issues that plague bioprocessing steps make atomization of biologically active macromolecules difficult. This section will begin with a review of nearly all the classic atomization techniques invented; we will compare and contrast these methods in regard to their ability to sustain molecular conformation from large micron-sized linear polymers down to less than 30 nm for proteins. The goal here is to establish the mechanism for degradation in each technique and to suggest a variety of procedures to help mitigate these issues.

4.1.4.1 Common Techniques Employed in Processing and Delivery

The generation of an aerosol is as varied as the methods for manufacturing macromolecules. All employ some sort of external force to divide the liquid bulk into individual droplets. Some methods employ aerodynamic forces, mechanical vibration, or pressure oscillations, whereas others harness electrical attraction and repulsion.

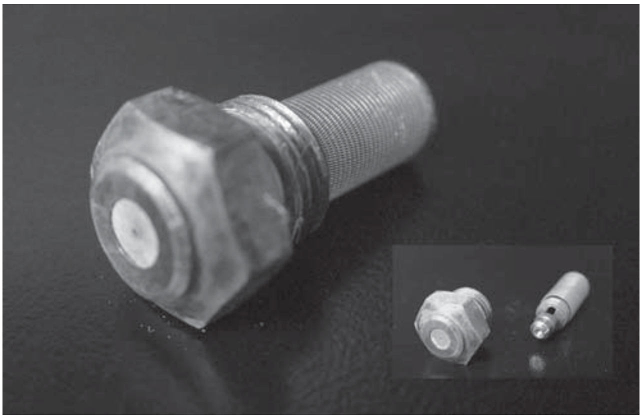

Figure 4.1-6. Photo of a Spraying Systems, Inc. hollow cone misting nozzle.

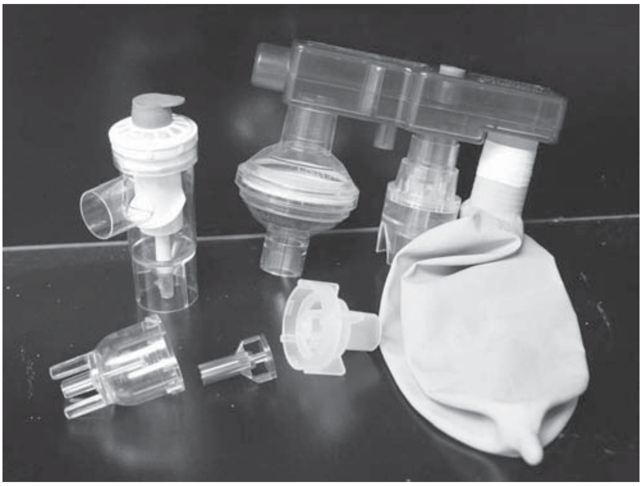

Figure 4.1-7. Photo of various commercial jet nebulizers.

Pressure-driven devices (Figure 4.1-6), such as pressure swirl atomizers, use aerodynamic drag at the gas–liquid interface to amplify natural disturbance to pinch droplets off liquid sheets and columns. Finer mists can be generated by adding a centrifugal force to the process that must overcome viscous damping and surface tension.

Jet nebulization (Figure 4.1-7), the cheapest and most common aerosol device in the pulmonary delivery arena, uses driving gas to accelerate liquid from a reservoir and achieve primary atomization. These primary droplets then hit an obstruction that causes splashing and spreading, which generates secondary droplets in the 1- to 10-μm range.

Ultrasonic nozzles use a metal horn geometry to amplify a small peizoelectric vibration. These vibrations drive surface instabilities along a thin film and generate droplets of very uniform size, but at low flow rates.

The details of how ultrasonic nebulizers create an aerosol is limited. A piezoelectric ceramic drives a pressure disturbance within the fluid at a rate of 15 to

Figure 4.1-8. Photo of an Aeroneb Pro vibrating mesh atomizer.

19,000 kHz. These pressure waves can form small capillary wave crests at the surface of the liquid or on a central fountain that ejects small liquid droplets from the crest. A third hypothesis is that cavitation events within the liquid cause large pressure singularities that eject liquid mass out from the liquid pool. Most likely, combinations of all three of these phenomena work to generate a fine aerosol suitable for inhalation.

Vibrating mesh technology (Figure 4.1-8) uses microfluidic manufacturing techniques to create arrays of small orifices that act as nozzles. Liquid enters these pores via capillary action but are ejected when a high-frequency vibration is imparted to the mesh using a piezoelectric crystal. The droplet uniformity is high and velocity low, making them excellent for respiratory applications.

Fine aerosols can also be generated at low flow rates by creating a potential force between a charged fluid and a ground plate creating a charged jet stream. The charged jet stream breaks into droplets when electrical stresses overcome the surface tension of the fluid. The final size of these droplets are a function of fluid properties (i.e., electrical conductivity, surface tension, density, viscosity, and dielectric constant), fluid flow rate, and applied voltage.

4.1.4.2 Degradation Behavior of Linear Genomic DNA

The degradation behavior of large molecules in atomizers can be correlated with turbulent length scales when it is the only mechanism acting on the system. Figure 4.1-9 demonstrates that when large DNA (7 μm) is atomized by various system; only those with very large turbulent length scale maintain structural integrity.

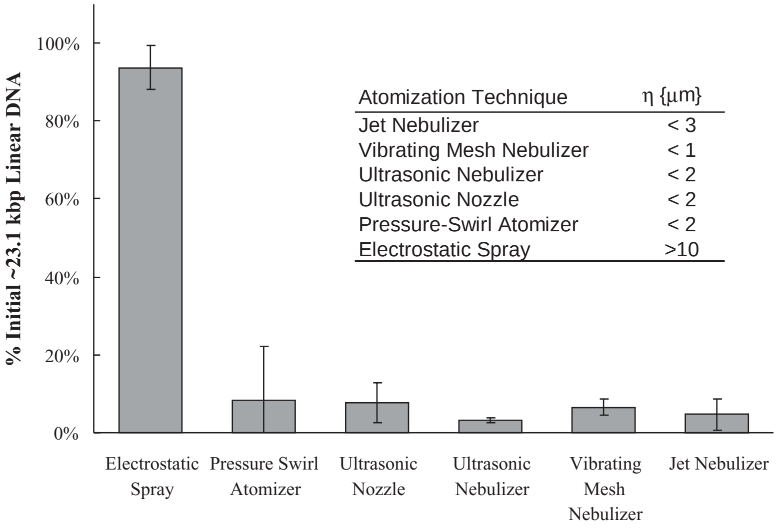

Figure 4.1-9. Degradation behavior of 23.1 kb genomic DNA after atomization. [23].

4.1.4.3 Degradation Behavior of Plasmid DNA

The structural degradation behavior of 5-, 10-, and 38-kbp plasmid/cosmid DNA in all atomizers presented so far has also been thoroughly studied. Lentz et al. [47] found that the jet nebulizer, vibrating mesh, and ultrasonic nebulizer are ineffective for all sizes. This is due to the extremely small turbulent length scales featured in the jet and vibrating mesh nebulization, and due to cavitation events nucleated at the DNA during ultrasonic nebulization. The ultrasonic nozzle is only suitable for very small molecular sizes based on length scales, whereas the pressure atomizer and electro spray seem to perform well over all size ranges.

4.1.4.4 Applications to siRNA Molecules

This chapter is focused on the effect of bioprocessing on proteins and plasmid DNA, but the use of small interfering RNA molecules to silence specific genes is gaining much attention and is currently being tested in clinical trials. Therefore, we thought it would be useful to briefly discuss how the principles described above for DNA might apply to small (≈21 bp), double-stranded RNA molecules. Our laboratory recently undertook an investigation to determine whether these small biopolymers would be degraded during aerosolization. Previous work in DNA indicated that jet nebulization is one of the worst processing techniques; thus, the degradation behavior of a 21-bp siRNA with a calculated melting point of 46°C was subjected to aerosolization by a jet nebulizer (in contrast, plasmid DNA typically has melting temperatures above 100°C). Because these biopolymers are much too small to experience significant shear stress, they are more likely to denature (separation of the two strands in the double helix) than break a phosphodiester bond in their backbone. Degradation can be observed by using molecular probes that bind specifically to double-stranded oligonucleotides (not single-stranded) and

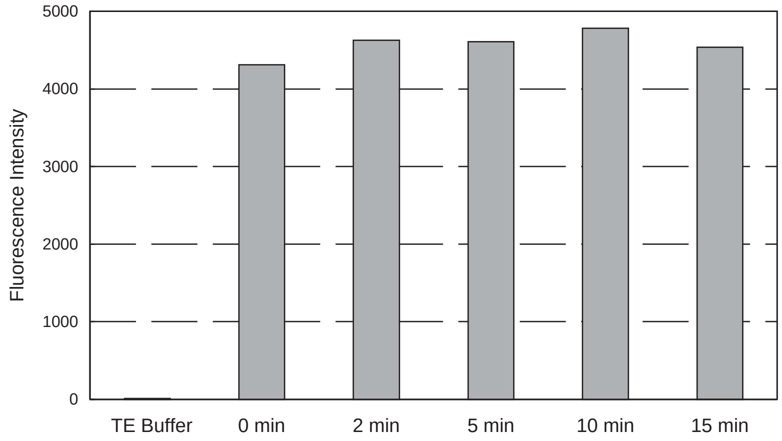

Figure 4.1-10. Changes in fluorescence intensity during nebulization of 21 bp siRNA with Pico Green fluorescent probes [Zelles-Hahn, Anchordoqury, and Lengsfeld, unpublished data].

fluoresce upon binding. In our experiments, we verified that Pico Green fluorescence was practically eliminated when the siRNA molecule was incubated above its melting point. Upon cooling to temperatures that allow annealing, Pico Green fluorescence was restored. When the siRNA was aerosolized for progressively longer times at room temperature, no change in fluorescence was observed (Figure 4.1-10). This indicates that even siRNA molecules with relatively low melting points remain double-stranded upon aerosolization with a jet nebulizer. Although it is possible that siRNA molecules with lower melting points might exhibit denaturation, sufficient stability can usually be achieved by increasing salinity to enhance the double-stranded form.

4.1.4.5 Degradation Behavior of Proteins

Work by Maa and Hsu [37] and Maa et al. [36] definitively demonstrated that protein degradation during atomization processing steps is due to the large interface to which the molecule readily diffuses (Figure 4.1-11). Here the application of a small shear stress is all that is needed to facilitate the unfolding of the amphipathic molecule to preferentially expose hydrophilic moieties to the gas phase (i.e., remove them from water). Thus, increased protein degradation is observed at smaller droplet sizes (Figure 4.1-11). In less-stable therapeutic proteins, we have seen batch-to-batch variability, whereas others have had success with using excipients, e.g., sugars and buffers. However, our group and others (Gomez et al. [48], Dunn-Rankin) have observed little to no degradation of protein during electrostatic spraying. This maybe because we all used relatively stable proteins or because our droplet sizes were not well controlled at sizes below 10 μm, but we have not experienced the severe difficulty found with numerous other techniques. Electrosprays are difficult to control with an aqueous solution, so if droplet uniformity and performance is needed over a broad range of conditions (or worse variable conditions), this is not the technique for you.

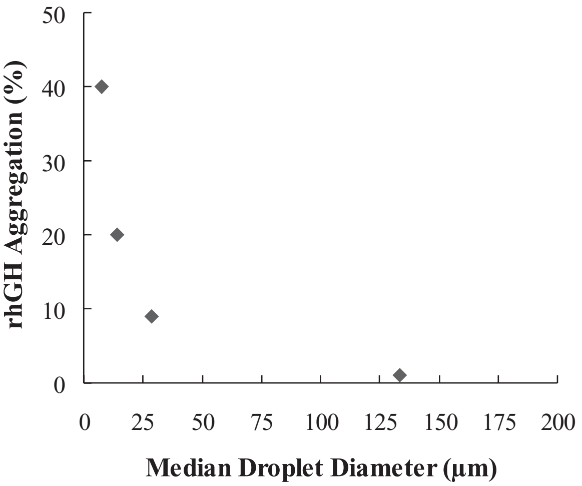

Figure 4.1-11. Data from Maa demonstrating protein aggregation of rhGH was linked to the surface-to-volume ratio of the liquid droplet produced during atomization [36, 37].

4.1.5 SEPARATION TECHNIQUES

The separation and purification steps in macromolecular bioprocessing typically cause the largest loss of product. The sources for molecular degradation presented above apply to these techniques, but it is informative to understand the classic approaches used today as well as methods under development for the future. To this end, the following sections provide a general overview of the subject followed by a brief review of molecular scale technologies currently under investigation.

4.1.5.1 Classic Approaches

Structural changes and contamination must be limited for macromolecular therapies to become a clinical reality. Current techniques for assessment, detection, and separation continue to struggle to meet industrial needs; a novel high-throughput, integrated system capable of qualifying and separating contamination from the bulk is highly desirable.

Conventional DNA purification techniques have been adapted from principles governing protein purification, but the copurification of *E. coli* chromosomal DNA with the desired plasmid presents a unique challenge. Cell lysis, differential precipitation, enzymatic digestion, column chromatography, desalting, buffer exchange, and sterile filtration represent the typical processing steps. The large size of genomic DNA makes it especially susceptible to shearing, which results in fragments that are similar in size to the desired plasmid. Due to their similar size and virtually identical chemical composition, it is difficult to separate the fragmented genomic DNA from the plasmid product. As a result, contemporary plasmid purification protocols sacrifice approximately 30–50% of the therapeutic plasmid in an attempt to minimize genomic DNA contamination. The most common large-scale purification method is column chromatography where separation is achieved largely based on molecule size using anion exchange, size exclusion, and reverse phase. Although

a single pass is relatively effective for proteins (i.e., >95% purity), plasmid purification usually requires more than one of these columns to achieve acceptable levels of purity. In-process quality assessment is essential to biopharmaceutical development as the quality of the product is dependent on the initial stages of growth through every step of purification. Currently, in-process quality assurance tests are conducted off-line using electrophoresis and high-preformance liquid chromatography (HPLC) to assess plasmid concentration, hybridization to measure *E. coli* genomic DNA contamination levels, immunological assays for protein contaminations, and a standard *Limulus* amebocyte lysate assay to assess endotoxin levels. However, the major challenge is the detection of small quantities of bacterial genomic DNA in the large bulk quantity of plasmid DNA. This can be achieved with amplification techniques, but as with many of the other assessment techniques, this must be conducted off-line in a time-consuming manner. As a result, it is not determined whether batches are satisfactory until processing is completed. Clearly, it would be advantageous to develop techniques that allow process modification in real time to improve quality essential to sustaining the batch. For example, these sensors could be used to optimize production rates. High throughput usually requires higher flow velocities, which are known to fragment large macromolecules, but conservatively low velocities lead to long batch production times and revenue limitations. Real-time detection of contaminating DNA fragments could signal the operating system to reduce the energy per mass input to the system, lowering turbulence-induced fragmentation and thereby continuously optimizing throughput and product quality regardless of processing scale. A technique that probes individual molecules would provide an opportunity to overcome this multimillion-dollar problem. Because probing individual molecules requires a device with length scales at or below the molecular length scale, the answer must lie in a nanotechnology-based solution.

4.1.5.2 Novel Molecular-Scale Probing Concepts

Some work already exists in the area of using micron or submicron fluidic devices to enhance DNA separation techniques. Most of these techniques use electric fields or electrosmotic flow [49] to induce movement in these macromolecules. Electric field-induced diffusion through cylindrical or rectangular obstacles set at an angle of 45° to the field has demonstrated that small molecules move faster than large ones, making continuous sorting possible [50, 51]. Switching the electric field in 10-s intervals can provide enhanced separation rates by slowing the larger molecules to a greater degree [52, 53]. Instead of rectangular post arrays, as Han and Craighead [54] demonstrated, requiring the macromolecule to change conformation by altering the channel dimension from thick to thin, can create entropic traps that collect a particular size range. These confinement channels (post array limited or trap geometries) separate DNA fragments of a different size using the fact that as channel walls prohibit some molecular conformations as channel size approaches the molecular scale or smaller [55–57]. These limitations result in excess free energy (or an entropy gradient), which may impart a measurable force. For example, Turner et al. [55] report forces on the order of femto-Newtons. If entropy is proportional to molecular length, matrices can be designed such that only a specific length scale will have the necessary inherent force to move through the system. Yi

and Lengsfeld [58] have built off these concepts and computationally explored the development of converging channels to alter the speed and compression of molecules at the molecular scale. Their new approach to analyzing molecular scale behavior is computationally efficient, and it will enable extension to circular and supercoiled DNA conformations where the excess energy generated by confinement might not only be governed by molecular length, but also by structurally restricted degrees of freedom inherent to the supercoiled and open circle conformation.

4.1.6 CHAPTER SUMMARY

Remember when dealing with proteins that (1) the small physical size of the molecule is below the continuum limit and thus the molecule is not susceptible to shear induced degradation; (2) structures that control activity are a result of relatively weak hydrophobic interactions and hydrogen bonds that result in an unstable active structure; and finally (3) proteins are surface active due to the amphipathic nature, and thus large surface-to-volume ratios should be avoided.

Double-stranded RNA molecules, although only discussed in a limited fashion, hold the best traits of DNA and proteins, i.e., siRNA's structure does not lend itself to high surface activity, and thus degradation by absorption to solid– or gas–liquid interfaces is not an issue. Furthermore, siRNA's small size is well below the continuum limit, and therefore, the molecule is not susceptible to shear-induced degradation.

When dealing with plasmid DNA, it is important to remember that the size straddles the continuum limit; thus, the molecule may be susceptible to hydrodynamic forces, especially turbulence. Reductions in power inputs to the fluid volume must be regulated to keep the Kolmogorov length scale larger than the molecule; alternatively, mitigation techniques using condensing cationic molecules must be used. Overall, the best-performing aerosolization devices are those with low residence times, such as pressure swirl devices, and low turbulence systems free of cavitation, e.g., electrostatic sprays.

4.2.1 BIOPHARMACEUTICALS

Biopharmaceuticals are drugs, vaccines, and pharmaceutical agents (typically therapeutic proteins or polypeptides) developed or produced using techniques of biotechnology [1]. In many cases they are complex proteins exhibiting varying levels of heterogeneity [2], derived from recombinant gene expres-sion or hybridoma production systems [3]. These products of biotechnology generally are classified as biologicals by regulatory agencies [4]. Specific categories of products include monoclonal antibodies and other recombinant proteins produced in cell culture, enzymes, hormones, soluble receptors, growth factors, imunogens, blood and plasma products, and animal-derived products [3, 5]. Biopharmaceuticals range in molecular weight from a low value of 22,000 for human growth hormone to about 150,000 for an intact immunoglobulin [6]. These agents are among the most expensive products to manufacture, with typical inventory costs of hundreds to thousands of dollars per gram [3]. There is also intense pressure to introduce a product to the market in a timely manner [2, 7] to recover research and facil-ity investments. Consequently, the reliable production of quality biopharmaceuticals is of the highest importance, translating into an intense focus on the creation of an effective and economical production process. Process validation is a key mechanism to successfully accomplish the task of process creation.

4.2.2 PROCESS VALIDATION OVERVIEW

4.2.2.1 Definitions

Validation derives from the Latin word *valere* meaning “to have the power” [8], presumably referring to the power to prevent an unexpected and undesirable occurrence. It establishes that the process used is reliable and reproducible [9]. The level of control implemented is supported by scientific knowledge of the culture and product, along with equipment capabilities [10]. The U.S. Food and Drug Administration (FDA) definition of process validation (PV) is documented evidence to

provide a high degree of assurance that a specific process consistently produces a product meeting predetermined specifications and quality characteristics [11]. The International Conference on Harmonization (ICH) definition is similar, stating that process validation is documented evidence that the process, when operated within established parameters, performs reproducibly and effectively to produce an intermediate or active pharmaceutical ingredient (API) meeting predetermined specifications and quality attributes [11]. Most simply stated, process validation provides a high degree of assurance that process will routinely achieve the stated goals [12]. It accomplishes this goal by verifying product and process specifications to determine their weaknesses and reproducibility [13] and by demonstrating at which steps contaminants are removed and the product stream achieves acceptance criteria [14]. A verification of process consistency is conducted, highlighting the ability to produce essentially the same product (with the same safety and efficacy) over time, despite normal variability in operating conditions [12]. Consistency of multiple batches is demonstrated at full scale, with specific focus on the process operating in a consistent manner, reproducible removal of contaminants to acceptable levels, and monitoring parameters that demonstrate this consistency [14].

Process validation for biopharmaceuticals is somewhat different in application from traditional pharmaceuticals because the technology is different, but the theory and principles are similar [15]. Biotechnology quality control is defined by the individual production process and the product itself [16] because quality cannot be tested into the product [4]. The manner in which the biopharmaceutical is produced is part of its description; thus, biopharmaceuticals are characterized by chemical structure as well as by operational definition [17]. Few doubt the need for process validation, but there is disagreement and confusion about what needs to be validated and how to perform it [18]. Operational definitions of process validation have been developed to suit the philosophies of individual companies [3]. Thus, there is increased interest in developing industry guidelines for the design and performance of validation studies [19].

The term *validation* has different implications under different circumstances, and thus, its use can be confusing [19]. Furthermore, the term *validation* has been used interchangeably with other terms such as *performance qualification* and *process characterization*, when discussing process as well as equipment testing. Recognizing that individual firms distinguish among these terms differently, there has not been an attempt in this chapter to create strict definitions that artificially introduce restrictions where none exist currently. Rather, the terminology employed has remained flexible regardless of the specific terminology used in the source material, such that it reads as internally consistent. In addition, the focus of this chapter primarily is on process validation for steps required to produce bulk biological substances, but the principles discussed also can be applied to the final processing steps involved in formulation and packaging.

4.2.2.2 Purpose and Benefits

Validation has been a critical success factor in product approval and ongoing commercialization [14]. It serves as a formal link of the process to the product [10], focusing on quality but often concurrently addressing critical business concerns. Each Good Manufacturing Practice (GMP) step must be controlled to maximize

the probability that the finished product meets all quality and design specifications [14]. In addition, each step must be evaluated for its function and effect on product identity, purity, potency, safety, or stability [12, 20]. An unvalidatable process is unacceptable and unreliable from both regulatory and manufacturing (i.e., business) perspectives [12].

There are two goals of process validation: (1) to support the safety, efficacy, and quality of the product; and (2) to identify major sources of process variability so appropriate controls can be implemented to provide consistency [10]. Achievement of these goals demonstrates that potential risks have been adequately reduced and assures products consistently possess the required established quality attributes [12]. Weaker points of the manufacturing process are uncovered and strengthened during the validation effort [12]. Thus, process validation deepens process understanding, which in turn decreases the risk of processing problems/failures, defect costs, lot rejections, reworking/reprocessing, product shortages, or regulatory noncompliance [3, 21]. Assurance of process consistency maximizes productivity and increases cost efficiency. It influences process economics in many ways; one example is through the reduction of in-process control and endproduct testing [21] by reducing the number and scope of quality control tests per lot [12].

4.2.2.3 Scope

Process validation is the culmination of all qualification and validation activities, representing process testing in its entirety [22]. It is a dynamic process varying in depth according to the product life-cycle timeline, spanning from initial process design through ongoing commercial operation [14]. Its execution can be envisioned as creating a "design space," a multidimensional space that defines how different variables interact [23]. This design space (1) establishes the process ranges demonstrated to provide quality assurance, and (2) defines areas in which process adjustments and refinements may be undertaken without regulatory involvement. The dimensions of this design space are based on the scientific understanding of critical process parameters that has been created through development studies [23, 24].

For a product, the overall list of subcomponent systems to be validated includes equipment, facilities, utilities, computers (including software and controls), processing environment, analytical methods, and operating procedures (e.g., cleaning and sterilization), as well as the process itself [14, 25]. Before process validation begins, these subcomponent systems are qualified [11]. As process validation rests on the fidelity of the qualification of the subcomponent systems required for process operation, the undetected shortcomings of these efforts can compromise subsequent process validation [10]. As with equipment qualification, process validation is most effective when conducted in combination with effective process and facility design efforts [12]. Also, as with equipment qualification, predefined acceptance criteria and action plans in case of test failure are devised [26]. The use of predetermined specifications serves to reduce the goals of a validation program to actual practice [12], assisting in implementation.

Process validation for the production process is only one means to assure product consistency. Other factors include quality control for the final product, in-process assays, raw material controls, appropriately designed facilities, personnel monitor-

ing and training, and environmental monitoring [4, 10, 27]. Additional factors that become concerns for multiproduct biopharmaceutical facilities include (1) segregation of materials, personnel, and equipment; (2) cleaning and product changeover; and (3) product cross-contamination [4]. Characteristics of biopharmaceutical processing that generate specific areas of quality control concern are large, complex product molecules, complicated manufacturing systems, long production times, and pooling of fermentation lots before isolation [4]. Other product quality concerns include genetic stability, product yield and stability, host and nonhost cell component contamination, and posttranslational processing, including glycosylation and folding [16]. As biopharmaceutical manufacturing processes are complicated with multiple steps and extended production times, adequate in-process testing, thorough process validation, and appropriate measures to eliminate adventitious agents are necessary [28].

4.2.2.4 Regulatory

The completion of process validation represents the point at which the science of the process is ready to be explained to regulatory agencies [14]. Process validation data are initially presented to the regulatory agency during application submission [11]. These data set the bar by which the process is to be judged during future inspections, and consequently, one of most common FDA 483 observations is the lack of process validation [14]. As manufacturing is a key factor in achieving the required quality and safety of biotechnology products [27], process validation is a regulatory requirement for product licensure, and limited process validation is considered essential even for product destined for clinical trials [3]. Process validation is required in license submissions for all products regulated by either CBER or CDER [14]. There are added challenges for biopharmaceuticals, however, as process consistency often replaces detailed product analysis as a key method of quality assurance, and biologically based production systems contribute biological contaminants that pose safety risks [29].

It has been stated that validation should be written as if the FDA were the customer [14], and this approach still is valid because worldwide harmonization efforts are well underway [24]. Several guidance documents have been published in draft and finalized forms from various regulatory agencies and industry associations worldwide. Key documents are listed in Table 4.2-1. New guidance, as well as interpretations of prior guidance, is continuously published, suggesting that there is not yet one consistent approach to process validation. Additional guidance leading to the improved definition of process validation requirements and reduction in marginally helpful studies is welcomed by industry [3]. Several comprehensive publications describing the interpretation and application of process validation by industry are available, but terminology and definitions have become blurred and overlapping. A summary of various terms used is shown in Table 4.2-2. Consequently, the use of the term selected must be fully and consistently understood by authors, reviewers, approvers, executors, and auditors in the context of its specific application.

Pitfalls. Validation (consisting of process, equipment, and facility systems) is a costly and time-consuming investment with more resources believed devoted to its

completion than to the initial process development and production of clinical supplies [3]. The actual cost of process validation is thought by some to be uncontrolled and excessive because there is no consensus on how much is enough [30]. One key risk associated with biopharmaceutical product manufacturing is the failure to gather sufficient information to support process decisions when faced with issues arising in process validation, failure investigations, product specifications, analytical methods, and equipment qualification [30].

Common pitfalls associated with process validation are numerous. They include a lack of overall strategy, insufficient planning/management, delay in early consultation with regulatory agencies, inadequate product definition, failure to observe current GMPs (cGMPs) and follow standard operating procedures (SOPs), poorly defined cell bank genealogy, inadequate analytical procedures, confusion over participant responsibilities, excessive process changes after process validation completion, insufficient prior process characterization or qualification, starting process validation too early and before process finalization, poor validation study design/

definition, disagreement on evaluation/interpretation of results, and inappropriate acceptance criteria [8, 14]. When overall validation activities begin too late, the work required to validate methods, facilities, and/or processes typically has been underestimated [4], placing product launch at risk. When processes perform erratically during process validation, further investigation to uncover inadequate development or lack of control of one or more process variables is required, followed by additional validation studies [12].

Validation must be science based [31]. Sound science during process validation is the primary vehicle to reduce manufacturing costs while remaining compliant with regulatory expectations [30]. Overly complex plans contradict desires to be efficient, lean, and cost-effective. More intensely planned projects produce more efficient, lower cost, and higher quality products in a faster time frame [30]. Resulting risks for biopharmaceutical companies from ineffective process validation include patient (safety and efficacy), operational (safety, contamination, variability), financial (product loss, reputation, legal costs), and regulatory (FDA 483s, warning letters, recalls) factors [11].

4.2.3 EVALUATING MEASURES OF PRODUCT QUALITY AND CONSISTENT PROCESS PERFORMANCE

A streamlined, integrated, and comprehensive validation process is desired [32]. The key to achieving a manageable process validation design is determining which process variables can be relegated to a noncritical status or maintained under tight control. Only when absolutely necessary should parameter ranges be validated. Thus development studies are required to identify critical parameters, limits to their operating ranges, and those process characteristics and equipment that enable their tight control [32]. It is necessary to distinguish between measures of product quality and process performance (consistency) and to differentiate between release specifications (such as critical quality attributes, CQA) that are measures of product quality and process attributes that demonstrate consistent process performance. Validation studies are required to examine process parameter variations that cause yield losses by affecting product quality (i.e., critical parameters); they are not needed for process parameter variations that cause yield losses that do not affect product quality even though these losses can cause economic/business concerns [10]. A comparison of process validation terminology for variables is shown by Table 4.2-3. A recent document has attempted to clarify these definitions further [33].

4.2.3.1 Critical Process Input Variables/Parameters

The basis of all process validation studies is the demonstration of control of critical process input parameters for reproducible operation of a commercial-scale production process [11, 32]. Critical parameters vary among processes so they must be separately assessed for each new process [10]. As a typical process has hundreds of variables, critical process input parameters must be identified first, and then the extended range and normal (target) operating range for each critical parameter must be determined during process development and/or using historical data [11,

TABLE 4.2-3. Comparison of Process Validation Terminology for Variables (bold entries according to Ref. 33)

Term	Criticality		Process Position		Control	
	Critical	Noncritical	Input	Output	Controlled	Uncontrolled
Operational parameters	**X**	**X**	**X**		**X**

Acceptance criteria	X			X		X
Performance parameters	**X**	**X**		**X**		**X**
Process attributes		X		X		X

34]. Critical variables are identified using defined procedures combining elements of data analysis and scientific judgment and making maximum use of available data gathered during process development [20]. Various companies have developed differing decision matrices to determine critical parameters, some of which are based on formal risk analysis exercises. A critical variable is defined as a parameter whose operating range lies near the edge of failure [34]. Using this definition, in practice, most identified critical variables can be engineered out of the study. Critical steps are those steps that are difficult to control because they usually contain at least one or more critical variables that cannot be removed [34].

Critical control points (CCPs) are those locations within a process where control can be applied to protect product quality, specifically to prevent and eliminate quality hazards or to reduce them to acceptable levels [11]. For controlling hazards, the appropriate CCP may be positioned in the sub-sequent step from the actual hazard location. In addition, more than one CCP can be used to control a single hazard and more than one hazard can be controlled by a single CCP [11].

Critical parameters are studied next to determine the effects of their outer limit values on important process characteristics [10]. These critical outer limits must be attainable, accurate, robust, and scientifically based [11]. The control parameter range is the span of values that lies between two outer limits or control levels of a

parameter, and it represents the highest and/or lowest values of a given control parameter that actually are evaluated during validation [25]. It is not usually necessary to test both ends of the control parameter range for all parameters because scientific judgment can help determine which end of the range (high or low) is more likely to generate an adverse effect [10]. In other cases, testing of both the upper and the lower control limits for a large number of variables is required to identify worst-case conditions [35]. Acceptable ranges are narrowed, and experiments are repeated until the acceptance criteria are met using an iterative process that requires substantial execution [3]. The edge of failure is reached when an exceeded control parameter value adversely affects the process or the product in that process performance degrades or product fails [20]; however, it is not necessary to validate the edge of failure when validating a process [25].

One strategy is to select worst-case conditions that encompass the upper and lower processing limits of critical input parameters, along with situations and circumstances over the entire process (rather than only a single step) that together result in the greatest chance of process or product failure compared with the ideal or target conditions [31, 34]. Worst-case runs are long and complex because the entire process must be run completely, usually at large scale or full scale [10, 20]. Because the worst-case approach comprehensively in-cludes the direct effects and actions of all variables, if all experiments are successful, only a few studies are required [20]. To mitigate the high likelihood of failure of a worst-case study that results in repeating lengthy runs using revised conditions, worst-case runs are performed after factorial experiments, usually conducted at a smaller scale and of a narrower scope, have confirmed a satisfactory outcome under the proposed worst-case conditions [20]. A key philosophical weak point of the worst-case run strategy is that it is less probable in practice that all critical parameters experience simultaneous excursions to outer limits [10]. However, because all critical parameters are tested at their extreme range, the worst-case approach can identify interactions that design of experiment (DOE) methods cannot detect [10].

Regardless of the strategy employed, worst-case conditions for critical parameters are established and process validation assures that the process yields an acceptable product when challenged under these worst-case conditions [30], even though full-scale validation runs may not have been conducted at many of these worst-case limits. Then operating ranges and control limits are set to establish a process robust enough to produce acceptable product [14, 35], and full-scale validation runs are executed to demonstrate performance consistency. The assumption is that if the product is of acceptable quality when parameters are controlled at the outer limits of control ranges, then the quality also will be acceptable when these parameters are held within those control ranges. This strategy is analogous to the approach of using fractional cycles for validation and full cycles for actual operation when testing at cleaning and sterilization procedures [36].

For a controlled variable, several types of ranges exist around the set point (Table 4.2-4). The normal operating range (NOR), or the alert limit, is established by trending performance during clinical material or qualification lot production, and then assigning usually two or three standard deviations to the set point [20]. The proven acceptable range (PAR) encompasses all values of a given control parameter that fall between proven high and low worst-case conditions [25] and constitutes the proposed operating range [3]. The PAR should be greater than or equal to the MOR [3]. The maximum operating range (MOR), or the action limit,

TABLE 4.2-4. Ranges of Controlled Variables/Parameters in Order of Increasing Breadth

Controlled Variable/Parameter	Definition
Set point	Target
Normal operating range (NOR)	Alert limit, variations typically +/− 2 or 3 SDs from set point
Maximum operating range (MOR)	Action limit, product quality acceptable
Proven acceptable range (PAR)	Upper/lower worst-case conditions; outer or control limits/control parameter range; characterization, tolerance, or design space range; product quality acceptable
Limit/edge of failure	Unacceptable product quality, critical limit

is the range of the controlled variable within which product quality is acceptable, but not necessarily at the limit of failure; thus, if the variable value falls outside the MOR, it is not necessarily a failure [20]. As MORs can lead to a decline in process performance even if product quality remains acceptable, their frequent occurrence can become an economic or operational issue. The MOR should be sufficiently broader than the NOR to reduce the frequency of unplanned deviations [20]. The MOR can be extended based on manufacturing experience when excursions outside the MOR occur without adverse quality effects [20]. Overall, a demonstrated state of control is the condition when all operating variables that can affect performance remain within such ranges that performance is consistent and as intended [25].

4.2.3.2 Noncritical Process Input Variables/Parameters

Noncritical or operational parameters are process control set points that define the process recipe and show that the process can be executed consistently [14], but for which there is no established evidence of product quality impact [11]. If the process performance is consistent when noncritical variables are controlled within their ranges and if minor deviations (e.g., instrumentation inaccuracy) from these ranges do not affect product quality, then the variable or step is classified as noncritical [34]. Typical noncritical control ranges are wide and/or the variable/parameter is easy to control within the range [33]. Although noncritical parameters do not require further study [10], they also are controlled and monitored during process validation to reduce variability and operator error [11]. Recently, noncritical process parameters have been designated as key (ensuring operational reliability and desired process performance when maintained within a narrow range, significant impact but not failure within range) and nonkey (well-controlled within a wide range but a potential process or quality impact when outside range, no significant impact within range) [33].

4.2.3.3 Process Control/Input Parameters (Xs)

Process control parameters are operating variables that have assigned values to be used for control [25]. They usually are readily maintainable away from a point of

failure and within a tested manufacturing range by a feedback control mechanism [15, 35]. Control parameters may also be thought of interchangeably as input parameters, defined as operational parameters that can be controlled [32]. Control/input variables are those operating parameters with set points or ranges that define process execution, e.g., pH, flowrate, temperature, raw material amounts and specifications, properties, and hold times for in-process streams of prior steps [3, 14]; thus, these parameters can be validated as a range or as set points [32]. They are a subset of operating variables, all factors that potentially affect process control or product quality [25], that reasonably are expected to affect operation of a process step [15]. Control/input parameters also are referred to as Xs, analogous to independent variables [37].

All input parameters must be identified and demonstrated to be in control for the product to be in a validated state and the more tightly the range is controlled, the less critical the parameter is considered [32]. Validation steps are (1) identification; (2) classification as critical or noncritical, subclassification of critical parameters into those to be validated over a broad range and those to be validated as a set point with a narrow tolerance range; (3) validation execution for those critical input parameters with a broad range; and (4) validation execution using target set points for all process input parameters both critical and noncritical. The complexity of process validation is dictated by several critical process input parameters requiring either a broad range or a broad set point. As fewer range testing studies are required if more parameters can be tightly controlled, one strategy is to design tight control set points for as many critical process input parameters as possible (e.g., pH and temperature) [32].

4.2.3.4 Performance Uncontrolled Output Variables/Attributes (Ys)

Performance parameters reflect the outcome of a given step and indicate that the process gave the desired result [14] or quality attribute. They are uncontrolled performance variables [15] without a control action [35]. Their natural variation is defined by operating history; specifically, their variability is characterized from known historical data or estimated based on similar process performance [35]. Similarly, output variables reflect the step outcome and indicate performance was acceptable in terms of performance attributes for the step (e.g., titer and yield) or properties of the product stream (e.g., product homogeneity, purity, contaminant levels, and chromatography peak shape) [3, 14]. Still another term used is critical Ys (analogous to dependent variables), defined as product and process output variables that relate to critical quality attributes (CQAs), which are measurable outputs of each process step that are used to provide evidence that the step performed correctly [37].

An input parameter value is directly related to an output parameter or quality attribute; specifically, the output parameter of one unit operation often is the input parameter for the subsequent unit operation [32]. Equivalently stated, critical Ys (outputs or responses) from one stage often are inputs for next the stage [37]. Input parameters are assessed as to whether they significantly impact critical output parameters (e.g., product safety, identity, and efficacy), although the definition of significant varies among applications [32]. As all product quality attributes are not routinely measured during process development, some output variables are selected

based on a hypothesis that they are linked to desirable product characteristics [20]. An input parameter is determined as critical based on whether its operating point is located near the edge of failure and how well it can be controlled [32]. Input parameters then are prioritized based on the (1) output sensitivity to input variations, (2) step proximity to the final product, and (3) technical difficulty controlling the input within the specified range [32].

A more formal approach involves listing all key process input variables (KPIVs), factors [both process (physical) and product (chemistry)] that could potentially affect the mean and standard deviation of critical Ys (outputs) [37]. KPIVs are identified using brainstorming to generate initial information. Then the identified factors are reviewed to select those that should be maintained constant based on scientific judgment. Next, a review of process development data and additional experiments using DOE are used to identify those KPIVs which influence critical Ys [37]. Experimental results are inserted into a cause and effect diagram which statistically correlates input and output variables by constructing scatter plots [20].

4.2.4 BACKGROUND AND REQUIREMENTS

4.2.4.1 Types of Process Validation

All three types of validation, prospective, concurrent, and retrospective, are part of most comprehensive process validation programs that occur throughout a product's lifetime [3]. As a process approaches commercial status, validation approaches completion [25].

Prospective. Prospective validation is validation conducted before the distribution of either a new product or a product made under a revised manufacturing process where revisions may affect the product characteristics [37]. Prospective validation assures that process quality attributes are met before manufacturing operations have commenced [26]. It is based on a preplanned protocol [25]. Usually process validation is prospective [18] because a science-based, prospective validation is integrated as a continuous part of the development process [36]. Validation performed prospectively is relatively less dependent on in-process or endproduct testing [25]. Manufacturing lots can be released faster if prospective rather than concurrent validation is performed [26].

Concurrent. Concurrent validation is based on information generated during the actual implementation of the process [25], at the same time the marketed product is being manufactured [26]. Concurrent validation reduces the load at the time of regulatory submission because experiments are delayed until the manufacturing process is operating, but it places marketable lots at risk if a failure is detected. Until process validation (e.g., useful resin lifetime) can be established at the manufacturing scale via concurrent validation, a thorough performance analysis of the step (e.g., chromatography) must be undertaken for each manufactured lot, which is quarantined until the results are evaluated [26]. Thus, concurrent validation is based on batchwise process control and requires the use of validated in-process sampling and methods [25].

Retrospective. Retrospective validation is based on the review and analysis of historical information (e.g., batch records, in-process control testing, and stability testing) to reconfirm formally that control parameter ranges are appropriate [25]. Validation protocols sometimes are not needed, but the final results are formally approved. As with concurrent validation, retrospective validation requires batchwise control of the process and usually depends on in-process testing [25]. Retrospective validation has been found useful to augment (but not replace) premarket prospective validation for new products or changed processes [3]. The proven acceptable range (PAR) can be developed using the principles of retrospective validation to link acceptable product lots to normal/permissible values for process operating parameters [12].

Retrospective analysis applies to a large number of batches that have been prepared similarly by evaluating input/output parameter variation and relating it directly to batch product quality [10]. Specifically, it is most effective when many similar batches (e.g., tens to hundreds) exist. However, the observed range of some input parameters may be insufficient if they were tightly controlled during processing to effectively determine the impact of wider variations [10]. In cases where disparate historical data sources may not be directly comparable or missing, a screening DOE might be appropriate to establish that existing specifications maintain CQAs at desirable levels [37].

4.2.4.2 Aspects of Process Validations

Process validation starts with the identification of product quality attributes and justification of acceptance criteria, followed by a review of the risk analysis, execution of process development runs, and compilation of clinical material manufacturing data to set specifications considering process variability [11]. There is a greater focus on process validation for downstream steps rather than for upstream steps because downstream steps are associated with virus removal. Process validation is just one approach used to control virus contamination, however; others include cell bank characterization, in-process testing, inactivation procedures, control of raw materials, containment, and postmarket surveillance [6].

One significant source of variability in downstream process steps is changes in input streams between research/pilot-scale to full-scale [38]. Thus, input streams of high and low quality are used when evaluating the performance of the subsequent step in a pair-wise validation strategy [3]. Specifically, forward linkage studies are performed to understand downstream consequences for critical parameters [10]. When process steps are studied individually in a factorial approach, forward linkage variables are the output variables of given step that affect the performance of the next step [20].

Fermentation. A validatable fermentation process demonstrates a controllable method of growing cells that reliably express the biopharmaceutical product that can be reproducibly recovered if broth is harvested within a set of specified conditions that allow the product to meet its quality specifications [10]. The goals of fermentation process validation are to provide documented evidence that all aspects of the process perform as intended to generate consistent fermentation broths at harvest; this consistency in turn permits downstream steps to yield a

purified product consistently meeting its predetermined specifications [39]. Allowable ranges for culture conditions must be justified with scientific data [30]. Typical components of fermentation process validation include the fermenter sterile medium hold, inoculum train, fermenter inoculation, sampling, feeding, fermenter growth and production phases, and harvesting [9]. Specifically, the trigger for fermentation harvest (e.g., cultivation time, cell density, and viability) should be demonstrated to yield acceptable product [30]. CQAs defined for fermentation include product yield, cell density, and culture purity; critical process parameters include inoculum state, nutrient feeding scheme, and harvest time [40]. To ensure consistent broth quality, critical process parameters are best defined based on a culture physiological event rather than on elapsed cultivation time and are preferably those that exhibit distinctive online monitoring characteristics [40].

To link fermentation process input parameters to output parameters, specifically behavior in downstream isolation steps and ultimate product quality, usually a partial or total purification is necessary, which requires substantial labor to process samples [10]. Sample evaluation also is limited depending on the level of product characterization. Consequently, fermentation process validation has been viewed as less rigorous compared with other forms of process validation [10].

Viral Clearance Studies

Requirements. Any biopharmaceutical product using animal-derived materials during the manufacturing process has the potential for virus contamination [5]. The risk varies depending on the animal species and country of origin of the raw material [5] and the safety concerns associated with expression and amplification of the production system [13]. Process validation is conducted to determine the process capacity to remove and/or inactivate a virus using a wide variety of viruses in virus clearance studies. These studies complement analytical viral testing of product (at various stages of production, including the final product), starting materials (e.g., cell banks), and raw materials [5, 6]. Each process validation viral clearance study is reviewed individually to determine the log reduction performance versus requirements, which are set based on experimental limitations as well as on risk factors (i.e., number of patients and dosage) [5, 41]. In practice, viral inactivation testing is less rigorous than microbial sterilization testing, viral test methods generally are cumbersome with variable results (although PCR technology has improved technical robustness), and viral inactivating agents less robust than saturated steam [10]. Consequently, viral clearance studies are a substantial component of process validation.

Viral clearance can be demonstrated by two distinct mechanisms that both generate high clearance values. One mechanism is inactivation to reduce infectivity by chemical or physical means without affecting protein product stability. Methods include using pH (acidic, low pH conditions for pH inactivation for protein A, basic, high pH conditions for ion exchange resins), chaotropic agents (urea), ultraviolet irradiation, and solvent, detergent, or heat treatment [42–45]. The second mechanism is removal or partitioning to effect a physical separation of virus from the product. Methods include using chromatography (adsorbing protein and leaving virus in the column flowthrough or vice versa) and filtration (depth filters with a 20–40-nm pore size or ultra-filtration membranes with a cutoff of <300 kDa) [5, 7, 46–49].

Processing conditions significantly affect virus inactivation/removal performance. Specifically pH, buffer composition, protein concentration, flow rate, and product binding strength to resin influence chromatography steps [5]. Membrane chemistry and pore size, geometry, velocity and pressure of process streams, transmembrane pressure, and product load per area (volume/area, concentration/area) influence filtration steps [47]. When virus-inactivating buffers are used in chromatography, virus reduction is effected in the eluted product from a combination of removal and inactivation [46]. Analytical methods that can evaluate infectious as well as inactivated virus distribution in process streams can assist in understanding virus removal mechanisms [46].

Steps to be Validated for Viral Clearance. Process validation for viral clearance is conducted only on robust steps that can (1) be scaled down accurately and (2) reproducibly and effectively remove and/or inactivate a wide variety of potential viral contaminants under a wide variety of process conditions [5, 41]. The number of steps selected for validation depends on estimated viral clearance effectiveness based on historical data and target clearance values [5]. The FDA demands at least two different steps for virus reduction to guarantee safety and efficacy [7]. Potentially only two steps are required for antibody processes that use serum-free medium, but additional steps might be required if viral contamination risk is increased by using serum-containing medium [7]. Due to the use of live viruses to perform clearance studies, this work usually is outsourced to reduce cross-contamination issues [14].

The viral clearance reduction factor, the common logarithm of the ratio between the total virus loads before and after clearance, is established for viruses known to contaminate the production process [50]. Individual step clearances are combined to obtain the total clearance reduction factor. This reduction factor is used in combination with an assessment of step robustness to classify the step as effective (≥4 reduction factor and unaffected by small changes in process variables), moderately effective (4 > reduction factor > 1), or ineffective (≤1 reduction factor) with respect to virus clearance [50]. Clearance factors are usually multiplied if the mechanism is different for two separate steps and sometimes are added if the mechanism is same [51]. In other cases, if two independent steps have similar mechanisms of clearance, only one step is included in the summation because virus particles removed via that mechanism would only be expected to be removed in the first step [3, 5]. A total clearance of 12–15 logs is desired for lipid-enveloped viruses and fewer logs for nonenveloped viruses (e.g., polio) [30].

Virus loads in unprocessed, prepurified bulk (harvest samples) are quantified, typically via transmission by electron microscopy or infectivity, to estimate actual virus load versus the expected virus removal capacity of the process [47, 50]. Total virus clearance should exceed measured levels by at least 3–5 logs [47]. An example of a typical virus load is 10^5 to 10^7 RVLPs (retrovirus-like particles) per milliliter of unprocessed bulk from CHO cells [3]. Clearance factors of 15–20 logs are typical for murine retroviruses [3] and slightly more than for lipid-enveloped viruses. For most viruses besides endogenous retroviruses, however, there is no reasonable way to establish virus load in the bulk because these types of viruses should not normally be present. In addition direct testing methods are limited inherently because they are designed to detect only known and not known contaminants [5]. Thus, the

capacity of the downstream purification process to remove/inactivate known viruses should they be inadvertently introduced is defined for an extra degree of assurance [3, 5].

Spiking Studies. Often, if viruses are present in process streams, they are present at levels below analytical detection, so spiking-clearance studies are required for purification steps [3]. Spiking studies are repeated so that their reproducibility and variability can be assessed [5]. There are concerns that large spikes may not be representative of actual low-level virus behavior, however. Virus spikes are desired to contain as little protein as possible to reduce the impact of their addition on purification procedures [5]. Addition of a virus spike can alter protein concentration and viscosity, which can change elution characteristics and prevent the small-scale model from accurately predicting full-scale performance [52]. In practice, this goal is more readily achievable for non-lipid-enveloped viruses because enveloped viruses need a certain amount of protein to maintain stability [5]. Maintaining the salt concentration constant or evaluating product resolution and purity are two ways to demonstrate that the virus spike addition had no significant effect [52]. Consequently, there is a compromise between adding the highest amount of virus possible to more rigorously challenge and maximize the step clearance and maintaining the spike volume low (<10%) to avoid appreciable alteration of product composition and thus purification performance [5, 50].

Virus Selection. The goal of model virus selection is to demonstrate inactivation or removal of as many types of viruses as possible without compromising product activity and quality [50]. One virus can act as a model for a group of viruses with similar physio-chemical characteristics [5]. Model viruses should be possible to grow in cell culture to high titers and detectable using a simple but sensitive assay [47, 53]. Some viruses that are known to potentially contaminate starting materials grow quite poorly in cell culture; thus, some model viruses have been tissue-culture adapted and consequently may not be truly representative of wild-type viruses [41]. Another limitation of using model virus clearance studies is that model viruses may not behave similarly to actual viruses [5], but in many cases, model viruses are the only practical alternative.

Viral selection is based on (1) relevant viruses that are actual viruses (or of the same species as actual viruses and relevant to the host cell) that have been identified as contaminants (or potential contaminants) of the process, (2) specific model viruses that are closely related to actual viruses (e.g., same genus or family) and have similar physico-chemical properties, and (3) nonspecific model viruses believed to be representative of the spectrum of different virus physio-chemical characteristics [5, 50]. Nonspecific model viruses are used to show inactivation/removal of viruses in general and to characterize purification robustness [50]. Virus clearance studies should cover emerging viruses and viruses currently believed to be absent in raw materials. These concerns are not addressed when relying on direct testing to ensure safety, specifically consideration of future virus removal requirements in anticipation of future regulatory changes [5, 41].

Model viruses are selected that cover the range of physico-chemical properties of different virus species such as size (i.e., diameter and geometry), enveloped or nonenveloped, RNA or DNA, and single- or double-stranded genome [47, 51, 53].

Examples of model viruses selected for various characteristics are medium-to-large DNA/enveloped (Herpes Simplex I, pseudorabies), small/DNA/nonenveloped (Simian virus SV-40), small/RNA/nonenveloped (Sabin Type I Polio, animal parvovirus), medium-to-large RNA/enveloped (Influenza Type A, parainfluenza virus, Sinbis virus 1), and retrovirus/RNA/enveloped for murine hybridomas (Moloney murine leukemia) [3, 51]. Preference in the selection of specific model viruses is given to those viruses with significant resistance to physical removal/ chemical agents [47, 49, 51].

The number and type of viruses selected for spiking studies depends on the process materials (e.g., host cell) and product development stage [5]. Before phase I, virus validation must be conducted. Typical viruses studied are the murine leukemia virus as a model virus for retrovirus-like particles produced by murine cell expression systems (if applicable to the process) and parvovirus [50]. Before phase II, two to four additional viruses are selected that depend on the host cell and media origin [50]. It is advised to solicit feedback on virus selection from the relevant regulatory agencies depending on where the trials are to be conducted before conducting viral clearance studies for product destined for initial clinical trials [14].

Starting and Raw Materials. Starting and raw materials are chemical, biochemical, or biological components used in a biopharmaceutical manu-facturing process [53]. Quality control strategies for these materials have been developed based on the assumption that these materials may be contaminated with a virus [54]. Direct testing is limited by the fact that viral contamination can be nonhomogenously distributed in a raw material lot; thus, additional sampling has little value. In addition to being effective only if contaminants are homogeneously distributed, direct viral testing also only is effective if the contaminant is present at high titer, false positives can be investigated promptly, a broad spectrum of viruses are detectable by available assays, assays are adequately sensitive, and raw materials do not inhibit assay performance [54].

Cell Substrate. Since the genetically altered cell substrate is considered the main component in the production process, complete characterization plus evaluation of genetic stability are primary concerns [27]. Cell bank characterization in conjunction with product characterization (e.g., peptide mapping and amino acid sequencing) demonstrates the stability of the production process [55]. Cell bank characterization in conjunction with process validation and endproduct testing demonstrate product safety [55]. The most likely source of viral contaminations in a large-scale cell culture is the cell substrate [54]. Process validation plus cell bank validation provides assurance that final product is free of contaminating viruses and other adventitious agents [55]. There is little concern about viruses that do not replicate in the cell substrate [54], although nonreplication can be hard to demonstrate.

As one of the most critical raw materials in production is the cell bank, defined acceptance/rejection criteria and parameters under which the bank will be used are required [55]. Assays are performed on master and working cell banks to demonstrate stability and freedom from adventitious agents. Cells are analyzed both from master/working bank vials as well as from the end of the production run or a few doublings later [55].

During cell bank characterization, phenotypic characteristics of the master cell bank are established such as morphology, doubling time, product expression rates, karyology (for diploid cell lines), and isoenzyme analysis [55]. Genotypic characteristics also are established, including a description of the vector and inserted gene, copy number, restriction maps, and the nucleotide sequence of a cloned gene. Tests are conducted for adventitious agents such as bacteria, fungi, mycoplasmas, and a wide range of potential viruses (e.g., retroviruses) [55]. Routine stability programs are undertaken to monitor genetic stability with respect to phenotype, expression, and nucleic acid integrity [4]. A passage history (e.g., split ratio, storage conditions, and media used) is documented as well as the cell line origin [55]. As a result of these regulatory requirements, cell banks must be prepared by those well versed in the technical processing steps, but also well aware of regulatory requirements.

Media. Basal medium and other supplemental components are tested in a scaled-down mimic of the production process to determine cell growth and product yield, and the product characteristics are compared against reference materials [16]. It is necessary to assure that multiple lots of raw materials meet user specifications for performance and quality before selecting a vendor [52] and that at least one back-up vendor is available.

Step Hold Times. Documentation of bioburden and endotoxin control at the manufacturing scale over the entire hold time is accomplished via monitoring of intermediates using in-process samples [33]. In addition, small-scale studies can provide relevant worst-case data. The cumulative worst-case hold times are obtainable from the summation of the maximum individual unit operation hold times. However, this worst case is not required to be validated because such a series of unexpected events is likely to cause adverse drug quality as well as high endotoxin or bioburden. Instead, hold time studies are conducted for process solutions over the maximum durations that they will be held in tanks used for manufacturing [33].

Real-time stability data are required for reliably assigning expiry periods [4]. Stability data are obtained on the drug product stored in the proposed container under recommended storage temperatures [56], and this strategy has been applied for in-process streams. Although elevated temperature stability studies are used to accelerate product degradation rate to predict shelf-life [56], this acceleration methodology is usually not used to determine step hold times, which typically are a few days, weeks, or in rarer cases months. Additional stability and degradation concerns arise from the possible interaction of protein with stoppers and container closure systems and interaction of proteins with residual cleaning agents [4].

Contaminant/Impurity Clearance. Classes of contaminant removal include process-related, host-cell related, and product-related (e.g., aggregates, deaminations, and oxidations) substances [14]. Contaminant clearance studies can be used to avoid lot-to-lot acceptance criteria because safety margins of several logs of excess clearance are demonstrated [33]. In these studies, a contaminant is added to the input feed stream at the small scale, its recovery is measured at each stage of the

process step (e.g., column flowthrough, product pool, and regeneration fractions), and mass balance measurements are performed [51]. In a similar manner as viral clearance studies, each step's impurity clearance is challenged separately; then overall clearance is calculated by the product of individual clearances [51]. Impurity clearance studies are similar in concept to viral clearance studies without many of the virus handling and personnel contact safety issues.

Process-related contaminants include cell substrate-derived (e.g., host cell protein, DNA, retroviral-like particles, and endotoxin for *E. coli* cultures), cell culture-derived (e.g., inducers, antibiotics, and serum/media components such as antifoam), downstream-derived (e.g., enzymes, processing reagents such as glycerol and guanidine, inorganic salts, solvents, leachables, and ligands), and adventitious agents (e.g., virus, bioburden, and endotoxin) [33]. Cell substrate-derived and adventitious agents have been discussed. For many process-related contaminants (e.g., antifoams and enzymes), the key to tracking and demonstrating their removal is the development of a robust, sensitive, and yet straightforward assay.

A documented methodology is required for how product-contact materials are selected and purchased [57] for specific process use. Leachate process validation demonstrates that leachates are below limits of detection in each eluent pool; insignificant leaching occurs under severe chemical, time, and temperature exposure, and if significant leaching does occur, it is removed by the first few bed volumes of equilibration buffer [58]. Product extractable testing evaluates product contact surfaces in terms of materials of construction, process solutions or solvents, duration of product contact with various surfaces, product contact surface areas, and potential for extractables at various process stages [57, 59]. Materials are prioritized to direct studies at the most critical, high-risk materials. High-risk materials are based on the proximity to the final API, extraction capability of solvent, length of contact, product contact surface area, cytotoxicity of extractables, temperature, and inherent material resistance to extraction [57]. Example high-priority materials to assess are containers (e.g., stainless steel cans and plastic bags) for unfrozen and frozen storage of fermentation media/purification buffers/product intermediate streams, chromatography resins, valve diaphragms/transfer hoses, elastomers/pumps especially on the final purification skid, filtration membranes, final sterilizing filter, gaskets/o-rings especially on the final bulk tank, and silicone boot/tubing for the filling machine [57]. Material extractable data can be obtained in-house, or often it is available from the vendor.

Product-related impurities include truncated product forms, modified product forms (e.g., deaminated, isomerized, disulfide-linked, and oxidized), and product aggregates [33]. One way these undesired forms arise is during freezing and thawing owing to product concentration and pH gradients [60]; thus, the number of freeze/thaw cycles is minimized. Another way is from mixing liquids and dissoluting powders [33]. The minimum mixing time until homogeneity is determined for which results vary only within assay variability; maximum mixing times are established to avoid shear, oxidation, and/or product degradation.

Reuse of Chromatography Resin. It is necessary to demonstrate that chromatographic media can be reused, cleaned, and sanitized [61]. Used resins receive additional analysis not required with new resins such as the titration of small ion binding capacity, measurement of total protein capacity, comparison of flow versus

pressure plots to indicate particle size (and attrition), particle size distribution, total organic carbon (TOC) removal by cleaning solutions, and microbial contamination/endotoxin (LAL) analysis [58]. Exposure to cleaning/regeneration solutions, rather than contact with mild buffers and protein solutions during normal processing, is most likely to cause chemical degradation [58]. Three types of studies thus apply to resins: Column reuse studies verify continued resin performance after multiple uses followed by small-scale carry-over runs to confirm cleanability with multiple uses, characterization studies prove the process is robust and defines acceptable operational limits, and another third study type demonstrates that regeneration sufficiently sanitizes the resin and that the storage solution is bacteriostatic and fungistatic [61].

Columns reused for many cycles may not provide the same virus clearance as new columns [41]. Thus, virus spiking studies can be performed on new and aged resins to ensure clearance does not vary [5, 26]. Alternatively, virus clearance can be studied for new resins only, and performance attributes expected to decay before virus clearance ability can be monitored subsequently during actual reuse [62, 63]. Validation of the column resin cleaning and sanitization regime for virus inactivation also is necessary to demonstrate that bound virus does not accumulate and subsequently elute [41]. The appropriate number of reuses is selected by balancing resin cost with the time required to conduct the reuse study and the expected annual number of production runs [61]. Using resin to its functional lifetime maximizes its cost basis, which helps economics if the resin cost is high or the number of cycles is low [26]. Virus removal filters [64] also have the potential to be reused, and although less, if anything, has been published about their reuse, the performance characteristics necessary to demonstrate are expected to be similar to resin reuse.

4.2.4.3 Process Validation Execution Timing

The execution timing of key process validation elements varies according to the clinical phase of the product. As validation starts well before the last three lots before actual production [31], it is essential to consider the question of "how much process validation to do and when to do it" as early as possible [14]. Creating the validation package too early might result in redoing substantial portions [14]; creating it too late may delay product launch owing to an incomplete regulatory package. Process validation is a continual process and should be monitored closely for adherence to timelines, scope, and cost [4]. It evolves along with the development of the process and should be complete at the end of phase III [14].

At the preclinical product phase, critical and noncritical classification of process input parameters should be initiated [32]. Critical components of facility subsystem validation need to be essentially complete before phase I product manufacture [15]. For phase I, it is necessary to validate aspects of the process related to product safety (e.g., sterility, mycoplasma, viral clearance, impurity removal, and stability) [14]. Abbreviated viral clearance studies for model viruses/retroviruses and impurity clearance studies for host cell DNA often are acceptable, resulting in fewer downstream steps validated at this product stage [3, 5]. If viral clearance results are available in sufficient time, the results can be applied to developing the phase I process steps. All assays do not have to be validated at this stage, but some (especially product-specific ones) should be at least qualified [14].

For phase II, no specific process validation activity is required unless process improvement changes potentially affect prior phase I validation work [14]. Assay validation efforts should continue, however, so assays are ready for phase III validation and process development should be finalized before phase III [14]. Most process and assay validation activities begin in phase II and often extend far into phase III [4], occurring in parallel with phase II and phase III clinical material production [3]. Intensive process characterization often is delayed until after completion of phase II studies to conserve resources [65]. About 12–15 months are allowed for its completion before the process validation runs [65]. To minimize risk, if all phase II clinical data are not available, these activities can be ramped up slowly over the first few months. Raw material vendor audits should be performed between phases II and III before the manufacturing process is fixed [47].

Before phase III and process finalization, process robustness is evaluated via several scaled-down runs to quantify process variability [14]. These studies form the basis for the process validation program if they are well documented, use operational range extremes, and test different resin/raw material lots. Based on the resulting data, additional optimization to improve robustness is conducted. Fully developed analytical assays are employed during these pre-phase III scale-down runs to ensure the process meets the quality acceptance criteria. Then during phase III, any remaining assays are validated [14].

The heavy-duty process validation occurs in phase III when the process is better understood, a commercial process is in place, and there are likely to be fewer changes, adjustments, and mistakes that can cause deviations [14]. First equipment and other subsystem validation are completed and followed by process validation during three or more consecutive batches [14]. The master validation plan usually is approved during phase III clinical material manufacture [32], and it sometimes includes manufacturing equipment validation in addition to process validation [47]. Viral clearance studies are conducted with a greater number of model viruses possessing a greater range of virus characteristics, and the full range of impurity clearance and operating range validations is undertaken [3]. Mass balances are attempted, duplicate runs are tested, and resin lifetime studies are conducted [14]. Range testing validations typically are completed during phase III clinical production before the manufacture of qualification lots, except for viral clearance studies that are done earlier [32]. Thus, the pivotal phase III clinical studies are conducted using a fixed process with refinements already incorporated to achieve a robust and cost-effective process [15]. At this stage, operational parameters are defined and performance parameters are specified within wide limits until more extensive data are accumulated [15].

Process performance qualification typically is conducted during the production of qualification lots using target set points for all process input parameters to demonstrate consistency and reproducibility of input and output parameters [32]. This process consistency is demonstrated by multiple full-scale batches, for example, three-to-five consecutive purification lots from three consecutive fermentation lots, during which yield and product concentration are monitored at each step [14]. A failed lot can occur without resetting the count if it is due to a known assignable cause that is not process-related (e.g., operator error or equipment failure) [33]. The cause of noncompliance must be determined and corrected, the noncompliant product disposition designated, and any corrective actions taken recorded [11]. At

this stage, all assays are validated, all equipment and support systems are qualified, all personnel are trained, all critical input parameters with ranges are validated, and all critical input parameters with set points and noncritical input parameters are validated as a by-product of range-finding studies [32].

4.2.5 DEVELOPMENT SUPPORT AND TECHNOLOGY TRANSFER ACTIVITIES

4.2.5.1 Process Development

Role, Stages, and Plans. Process validation is an integral part of process development [13]. At the early stage of process development, the process is basic and unpolished [14] with purity ill defined and poorly controlled [2]. At the mid-stage, an optimized and more robust process exists, and by the end stage, the process is fully characterized, validated, and qualified [14]. During process development and scale-up, critical variables either are removed or else highly understood to develop a robust process [34]. Identification should start early and be based on literature knowledge, prior experience, or specific product information [32]. Some critical variables are identified via close in-process monitoring and thorough investigation when unexpected results are obtained [34]. Early, reliable, and accurate measurement of process variability increases the probability of operating and maintaining a robust, well-understood, and controlled process [66].

Successful process development establishes a clear logic path that streamlines subsequent validation design and testing [22, 32]. Process development serves to establish evidence that all key process control parameters and all control parameter ranges are validated and optimized to meet acceptance criteria before process validation [14, 25]. These acceptance criteria, specifically the critical process output parameters for scalability studies and range testing validations, in turn are derived from data obtained during development, preclinical, and clinical material production [32].

The greatest validation problems surface when insufficient resources and time are budgeted for understanding and optimizing production [14]. Development personnel require sufficient time and financial support for thorough validation and technical transfer activities, specifically remaining involved in process validation activities along with manufacturing personnel [2]. Consequently, development staff should understand compliance issues [13] to accurately anticipate the appropriate level of quality assurance applicable to process development studies [30]. Actual formal product development procedures have been recommended to ensure consistency [13], as well as capture best practices.

Process Development Documentation. As a considerable amount of relevant data is generated during process development, its documentation must be sufficient to support the selection of manufacturing steps [2]. Development work and decisions made during development are captured in development reports that support future regulatory inquiries [14] and demonstrate that regulatory requirements have been considered and addressed [30]. Development reports should highlight potential

weaknesses in the product and process design with the goal of suggesting which ones should undergo subsequent development and validation [13]. They also include an analysis of critical process parameters [13]. The first reports can be generated as early as before the initial product transfer to the process development group [32]. Additional reports are generated after the end of process development and before the start of process validation [32]. All of these reports need to be compiled and indexed so they are readily retrievable [13], perhaps stored in a database for easy access [14]. They serve as a resource for the product's process development history if an employee leaves (or is reassigned) or as training for new employees [14].

An upfront listing of the titles and scope of expected reports felt to be necessary to support process scale-up, validation, and regulatory filings is created and reviewed within the multidisciplinary validation team [30]. This listing helps identify required studies and form a process development plan that can facilitate future tracking of executed studies. Once the required component tasks and their execution order are established, this plan should be reviewed semiannually, adding accuracy and sophistication over time. Formal evaluation of the status of the process development plan demonstrates whether the project is on track and identifies deviations in time and cost. The interim goals, resources, and milestones listed in the basic plan focus efforts on priorities, permit staff to see how tasks are integrated, and reduce the likelihood of running out of time [30].

Process Characterization. The terms *process characterization*, *robustness*, and *validation* are sometimes used interchangeably, and consequently, the distinction among these terms consequently is blurred. Process characteriza-tion is more encompassing than process validation because process validation uses only a subset of the data generated from process characterization [15]. Characterization studies are similar in nature to validation studies except with less formal compliance to regulatory guidelines [12]. It is the part of the process development examining manufacturing ranges, robustness, and the edge of failure for a limited number of critical parameters [67]. For characterization studies, established scientific and engineering principles are used, along with methods that are not validated in the regulatory sense but are qualified scientifically with appropriate controls and written procedures. [12]. Typical causes of unexpected results in process characterization are inadequate procedures, or inadequate following of adequate procedures, and uncontrolled variables [37]. Process robustness provides assurance that the process will not fail when operating within defined control limits for key process variables [35]. This definition of robustness has been adapted from the ICH definition of analytical assay robustness (ICH-Validation of analytical methods, 1993), not from the guidelines for process validation [35].

Process characterization defines process capability and facilitates prospective process validation at the production scale [40]. Full process characterization is valuable in maintaining smooth manufacturing operations and minimizing lost batches, and it provides supporting information for lot release justification for atypical batches [15]. Its goals are to identify key operating and performance parameters, define control limits for key process parameters, demonstrate robustness of the commercial process, and provide technical information about the process [68]. The steps involved in process characterization include risk assess-

ments, scale-down model qualification, single-parameter ranging studies, parameter interaction studies, and worst-case studies [68]. Process characterization is conducted initially during the preclinical through phase III product stages and continues during the ongoing commercial manufacturing product stage [65].

The overall goals of process characterization are to (1) understand the roles of each process step, (2) become aware of the effect of process inputs (operating parameters) on process outputs (performance parameters) and identify key operating and performance parameters, (3) assure that the process delivers consistent product yields and purity in all operating ranges, and (4) develop acceptance criteria for in-process performance parameters [65]. Example operating and performance parameters for various process steps are shown in Table 4.2-5. Before beginning process characterization activities, advance preparation consists of examining available data and assessing risk, qualifying scale-down models, and developing process characterization plans. Execution involves four steps to achieving these process characterization goals: (1) characterize process performance ("process fingerprinting data") using screening experiments to eliminate additional parameters from further characterization studies, (2) identify interactions between key parameters, (3) establish process redundancy by determining the effect of feed quality on each unit operation, and (4) develop unit operation reports to document key operating and performance parameters and their respective ranges [65].

One recommended strategy for process characterization is to (1) measure as much as possible early in process development, (2) determine if changes in the

TABLE 4.2-5. Example Operating and Performance Parameters for Various Process Steps

Process Stage	Operating Parameter	Performance Parameter
Seed (shake flasks or fermenters)	Agitation rate Working volume Vial thawing conditions Growth temperature Number of generations	Time to reach transfer cell density
Production fermentation	DO/dCO_2 Broth pH Growth temperature Agitation rate Aeration rate Back-pressure Working volume	Titer Specific productivity Plasmid loss/genetic stability Growth rate/doubling time Peak growth cell density Harvest cell density/viability
	Percentage inoculum Transfer cell density for inoculum	Product quality (glycoform and/or sialylation distribution) Bioburden/adventitious agents
	Broth pH Point of nutrient feed initiation Nutrient feeding rate Osmolarity	Feed/acid/base usage Nutrient and waste by-product metabolism
	Point of induction	Time to induction

TABLE 4.2-5. *Continued*

Process Stage	Operating Parameter	Performance Parameter
	Concentration of inducer	
Filtration	Transmembrane pressure	Process flux and water flux recovery
	Feed/recyle/permeate flowrate	Cell lysis
	Membrane area/liquid volume or mass	Permeate turbidity
	Membrane geometry	
	Volume concentration factor/diafiltration volumes	
	Protein concentration	Yield
	Cell density/viability	Purity
Centrifugation	Centrifugal force	Cell lysis
	Feed/centrate flowrate	Impurity clearance (host cell proteins, nucleic acids, endotoxins)
	Feed/centrate solids content	
	Back-pressure	Centrate turbidity
Chromatography	Column pressure	Yield
	Column flowrate	Product concentration
	Column loading level	Purity
	Column load/wash/elution conditions (pH, conductivity, temperature, gradient slope, volume)	Impurity clearance (host cell proteins, nucleic acids, endotoxins)
		Viral clearance
	Buffer volumes	Ligand leakage
		Column HETP
		Peak shape
Precipitation	pH	Yield
	Conductivity	Product concentration
	Precipitating agent concentration	Purity
	Precipitate agent addition rate	Impurity
	Temperature	Precipitate yield
	Protein concentration	Supernatant turbidity
General	Pre- and/or poststerilization media/solution pH	Growth rate/doubling time
		Specific productivity
	Media/solution sterilization conditions (time, temperature, filtration)	

magnitude of each variable/parameter are relevant to process (or process model) performance, (3) select the relevant variables to be controlled and documented, and (4) collect, organize, and archive all raw data [69]. As the total number of factors to be tested can be very large, factors are combined and treated as single variables based on the experience gained during process development [60]. Variables expected to have similar effects are linked so that their cumulative effect will be additive [60].

4.2.5.2 Assessment of Process Risks

Quality assurance (QA) groups often desire a 100% guarantee of quality, leading to risk avoidance and promoting "over-validation" in the form of additional testing

and repetitive documentation that increases production costs [31]. Although absolute safety is a theoretical concept just like absolute sterility or product purity, it can be approximated using established scientific and engineering principles [12]. Risk analysis identifies the steps, critical factors, and parameters that affect product quality [11]. A documented risk analysis determines the extent of process robustness, summarizes results in a form readily presentable to internal and external regulatory personnel, meets regulatory requirements, identifies critical parameters for monitoring, increases process understanding, assists in troubleshooting, and, most appropriately, focuses process validation efforts where they are most warranted and beneficial [11]. It is first necessary to determine what level of each putative risk factor is considered safe, considering the intended clinical use of the biopharmaceutical (e.g., administration route, dose size and frequency, and total amount consumed) [12].

The process design must include steps that reliably remove or inactivate potential risk factors [12]. Rare, significant, and real risk factors must be distinguished from frequent, less significant, theoretical, or putative risk factors. In some cases, targets are more stringent for real and present risks than for putative ones, and reliance on removal/inactivation steps is less important if risks are purely theoretical. The list of putative risk factors is developed early in the process development cycle and then updated periodically as additional information and experience are obtained. Each potential risk is defined in experimental terms by assessing its biological, biophysical, and biochemical aspects. Two categories of risks are (1) potential pharmacological and toxicological effects of the product's active ingredient(s), and (2) other product components arising from the preparation process. Examples of specific risk factors are the presence of intact cells, adventitious agents (e.g., bacteria, fungi, mycoplasma, and viruses), endogenous retroviruses, residual cellular nucleic acid/proteins, microbial contaminants (e.g., endotoxin and proteins), and process chemicals (e.g., antibiotics, ligands, solvents, cleaning chemicals, inducers, and nutrients) [12].

Risk assessment provides a systematic estimation and evaluation of the risk potential for all components used in the manufacturing process, including the origin and fate of each raw material [53]. Risk assessment also estimates potential risks associated with the application of certain procedures during the manufacturing process (e.g., isolation, validation, and testing) by quantifying a procedure's robustness and susceptibility to errors. It assesses which contaminants have the highest probability of being present and then provides a basis to establish a reasonable and economical testing scheme [53].

Each risk factor must be identified and quantified in terms of its likelihood of occurrence and its severity [12]. After the initial first key steps of risk identification and quantification, the greatest risks then can be reduced [29]. Reducing the probability of a risk's occurrence is achieved via implementations such as process automation, tighter controls, or removal of open processing steps [70]. Reducing a risk's severity factor is achieved by process changes or product redesign [70]. In contrast, raising the probability of failure detection by increasing sampling and monitoring activities has been found to be the least productive and most time-consuming solution with little opportunity for automation [70]. If a significant risk cannot be reduced sufficiently, then the associated process step can be validated to provide additional performance assurances.

Risk Assessment Tools. Risk assessment tools (FTA, FMEA, and HACCP) can be used alone or in combination [11]. They are tools for problem prevention, requiring failure anticipation rather than analyzing failures that have already occurred [71]. After process characterization is completed, formal risk analysis exercises can be repeated so future focus can shift to newly uncovered unit operations and operating parameters requiring attention [65].

FTA. Fault tree analysis (FTA) is a deductive, top-down approach to failure mode analysis [11]. Its open-ended structure is readily expandable, making it helpful for complex problems [71]. The failure or hazard is assumed; then the combination of conditions or probable causes necessary for that event to occur is systematically defined by identifying how that high-level failure is caused by lower level, primary failures, specifically the failure of an individual component or subsystem. This information is presented in the form of a fault tree diagram with the assumed failure/hazard listed first at the top and the associated conditions/probable causes listed as branches with successive levels listed as further branches [11, 71]. Events at different levels of the tree are listed below the main failure event and connected by event statements and logic gates defined by Boolean logic [11, 71]. “And” is used if events need to occur together to cause the failure/hazard; “or” is used if the event alone would cause the failure/hazard [11]. As a fully developed FTA can be complex, special symbols are used to describe events and gates to simplify graphical representation of casual relationships between branches [71].

FMEA. Failure mode and effect [criticality] analysis (FME[C]A) is a preventative, bottom-up approach to identifying potential failures [11] that has been recently adapted to quantifying GMP risks [70]. FMEA has been applied to audit preparation, batch record review, production validation, change control evaluation, retrospective validation, trend analysis, and validation master plan development [72]. Although it includes identifying the effects or consequences of failure modes, it is a more practical tool and a structured guide to analyze major areas identified by the FTA [11, 71]. However, it is not considered as effective as FTA in identifying root causes for intractable process failures [71]. FMEA uses its structured methodology to facilitate identification of critical variables, specifically reducing 20 or more to 2–3 to permit efficient further optimization [72]. FMEA progresses over time, starting in the early stages of process development [11], and it is most successful if the process to be examined is clearly defined at the outset [71]. Overall, FMEA serves to (1) readily identify potential problem areas where operators must be especially alert and where intensified test procedures may be required, (2) define operational constraints and preventative maintenance actions for equipment, (3) provide information for planning performance qualification, (4) prioritize corrective actions and improvements, (5) foster interdisciplinary teamwork and communication, and (5) facilitate decision making throughout the development process [71].

The first step in FMEA is to develop a working matrix that identifies all information categories that are intended to be studied [67, 71]. A flowchart describing process steps serves as the left column of the matrix. An accurate description of each step helps stimulate thinking about how the step might fail. A list of reasons is generated describing why each step might fail to complete its intended function

(potential failure modes) and what would happen if failure occurs (potential downstream effects) [73]. All possible causes, however improbable, are identified that might result in failure; then the risk attached to each failure is evaluated using an established scale, for example, values from 1 to 5 [71, 73].

The next step is to rate the importance of the identified failure in terms of its probability of occurrence based on the controls in place (P), severity (S), and ability to detected (D), resulting in a risk priority number (RPN) [11, 70]. It asks the following questions: What could go wrong, what is the probability of its going wrong, what are the consequences of it going wrong, and can in-process or final product testing detect it when it does go wrong [72]? RPNs, also known as the criticality index, then are used to sort the identified causes/effects of failures, which enables FMEA to identify those failures posing the greatest threat to the manufacturing process [71]. P, S, and D are all rated between the low and high values; P and S directly increase with numerical rating, and D inversely increases with numerical rating. The RPN value is calculated by the product, $P \times S \times D$ [71–73]. If P, S, or D is completely unknown, then a high value rating (e.g., 5) is assigned [72]. Thus, in the worst case RPN = 125, and in the best case RPN = 1. In practice, RPNs only are calculated for the worst aspects of each failure to reduce workload and to permit identification of the most critical failures first without requiring detailed calculations for each identified cause [71]. Frequently, the highest RPN steps are those steps involving human intervention because P is typically 3 or more [72].

The output of an FMEA study is the list of preventative and corrective actions necessary to improve the manufacturing process that now can be prioritized based on RPN values [71]. An acceptable RPN should depend on the severity rating of the failure, specifically if S = 5 (high value), then the RPN should be ≤5, but if S is below 5, the acceptable RPN can be higher [72]. The RPN then can be recalculated after corrective actions have been implemented providing measurable proof of impact [71].

HACCP. Hazard analysis and critical control points (HACCP) is a systematic approach that is system-based to determine high-risk steps [11]. The definition of hazard includes both safety and quality concerns for biopharmaceuticals. An effective HACCP system reduces endproduct testing because sufficient validated safeguards are instituted [11]. HACCP provides detail and documentation to show process/product understanding through identifying parameters to control and monitor. Its stages are to (1) conduct the hazard analysis, (2) determine critical control points, (3) establish critical limits, (4) establish monitoring procedures, (5) establish corrective actions, (6) establish verification procedures, and (7) establish record-keeping and documentation procedures [11, 74].

4.2.5.3 Validation of Assays

Purpose. As biopharmaceutical products are large and complex molecules and no single test method is sufficient, product analysis uses multiple, different analytical methods strategically designed to be complementary with respect to selectivity and specificity [4, 27]. More sensitive test methods allow proof of greater removal of a putative risk factor [12], and the more key parameters that can be measured assure that process variability is understood and controlled [66]. However, it is important

to avoid setting product specifications at the assay's limit of detection [2]. Assays provide adequate in-process testing via process validation and a comprehensive assessment of the final product using a variety of analytical methodologies for identity, purity, potency, strength, safety, and stability [4].

Assay validation characterizes the assay performance so that the significance of the measured assay values obtained is readily understood [75]. Test methods should be validated when important decisions are to be based on the data generated [30]. Thus, the extent of method validation depends on the stage of clinical supply manufacture. The key elements of assay validation for a method are to establish reliability, the intra- and interlaboratory test variation, and relevance, the meaning of the results for a specific purpose [19]. The robustness of an analytical procedure (according to the ICH-Validation of Analytical Methods, 1993) is its measured capacity to be unaffected by small variations in controlled parameters and reliability under normal usage [35].

Scope. The scope of assay validation is to assess the essential test method performance characteristics of accuracy, reproducibility, repeatability, linear-ity, and limit of quantitation/detection [41]. A test method is evaluated for its readiness for assay validation against the following criteria: (1) description of the test basis and scientific purpose, (2) case for relevance, (3) proposed practical application, (4) statement of limitations, and (5) acceptable intra- and interlaboratory precision [8]. Before actual validation, the test method should be optimized and standardized [8], specifically controls necessary to invalidate inappropriate out-of-specification results should be incorporated [30]. Assays must be validated for each matrix in which samples will be run [75] and for its capability on a protein-by-protein basis [56].

Assay ruggedness also is measured in terms of the similarity of results from different laboratories, manufacturer's equipment, and analysts [2]. Interoperator, interday, and intraassay variations can be quantified by comprehensive validation [5]. Interassay (intermediate) precision is the precision of multiple determinations of a single sample analyzed in various runs [75]. Intra-assay precision or repeatability is the precision of multiple determinations of a single sample within one assay run. Interlot precision tests analyze values of aliquots from a single sample run using lots of different assay components. Finally, lot-to-lot precision is the precision of multiple determinations of a single sample analyzed using different lots of assay components [75]. These multiple types of variations must be considered so that release criteria ranges are not set too tight.

The limit of quantitation (LOQ) is the lowest concentration that produces a signal 10-fold above background, whereas the limit of detection (LOD) is the lowest concentration that produces a signal threefold above background [75]. The assay sensitivity and achievable concentration limits of additives define a "window of clearance," which is the difference (on a log scale) between the highest attainable initial contaminant/impurity concentration and the lowest detectable concentration (LOD) of that additive [12]. This difference is the amount that can be measured and thus the amount that can be claimed to have been removed by the process [12].

A low-level sensitivity is required for viral test methods to maximize reduction factors [5]. However, the ability to detect low virus concentrations is limited by

statistical sampling [5]. The probability of detection (POD) for low-level virus concentrations depends on test volumes, batch volumes, and test sensitivity [40]. The POD is high when sample virus concentrations are well above the test method sensitivity, the POD is lower when concentrations are at or below the test method sensitivity, and the POD is even lower for very low concentrations due to the low probability of obtaining a virus in the sample as described by the Poisson distribution. Test method sensitivity should be based on a POD ≥95% [40].

In-process and release (endproduct) parameters, both critical and operational controls, are controlled and monitored during production using assays [11]. In-process controls generate data at critical process steps, which serve as a basis for specification development for product intermediates [2]. Specific in-process controls, routine sampling, and monitoring at specific process steps are established to monitor key process outputs [32]. Information only tests are used postvalidation without preestablished acceptance criteria until sufficient data have been collected to statistically establish clear limits or else omit the testing [32]. Thus, sampling and obtaining data for information only is an important part of process validation that must be recognized.

Assay Types

Potency. Binding assays for quantitation use the binding of at least two molecules to form an interaction that withstands multiple washing steps, and they are the least variable [75]. Cell-based bioassays for potency use a cell line mixed with a sample to generate a cellular response that is quantified [75]. They have more variability [75] and are tricky to use to measure potency because the CV often is >30% [2]. Whole animal assays for potency are time-consuming and highly variable [75], and they have the typical disadvantages of *in vivo* tests in that they are expensive, inaccurate, slow, and raise animal ethics issues [19].

The development and validation of *in vitro* tests that correlate with potency, typically desirable for vaccines, is tedious and rarely successful, requiring thorough knowledge of the immune response after infection or vaccination [19]. An alternative approach is to demonstrate batch comparability and then assume identical properties *in vivo* [19]. For an increasingly greater number of vaccines, no routine animal potency testing is being conducted because the product is well characterized, critical production process steps are controlled, immunology knowledge permits functional test development, analytical knowledge permits antigen characterization, and test procedures are becoming harmonized and validated [19].

Impurities. Analytical methods for impurity clearance require sensitivities capable of demonstrating sufficient clearance to well below safety margins [33]. rDNA technology has stimulated the development of a wide variety of assay types [16]. Specifically, PCR is used to understand how manufacturing steps impact retroviral clearance due to its high precision, high throughput, and low cost [76]. Typical testing for in-process impurities includes endotoxin, host cell and other proteins, DNA, viruses, and altered protein forms (e.g., proteolytic clips, deamination, oxidized methionines, and amino acid substitutions) [16]. Clearance of host cell proteins is measured using immunoassay [50]. Host-cell DNA is radiolabeled by nick-translation and then measured in column fractions (also radiolabeled host-cell

proteins), and it is measured directly in production streams [51]. Cytotoxicity and interference testing using non-virus-containing samples are performed to ensure that sample matrices in a viral clearance study do not adversely affect the ability to titrate virus [5]. These tests are performed well in advance of the actual validation so that conditions may be found for which dilution is not required, and thus, assay sensitivity is not reduced by dilution [5].

There is a lack of practical laboratory assays to detect bovine spongiform encephalopathy (BSE)-like agents so the potential introduction of these agents into the process must be controlled by avoiding bovine-based materials, using materials from low-risk bovine tissues, and/or sourcing materials from countries with good BSE control measures [21].

Typical testing on final purified bulk includes those tests conducted with in-process testing plus total protein content and potency [16]. The final product (sterile filtered, filled and sometimes lyophilized, then packaged into vials and ampoules) is tested for sterility, pyrogenicity, particulates, content uniformity, identity, excipient chemical content, potency, and protein content [16].

Standards. Key to the success of any assay method is the availability of a reliable standard. A primary standard is one recognized by a national or international agency, whose characteristics have been established by collaborative effort [77]. Secondary standards are calibrated against primary standards. Reference material is used for the evaluation of other materials to generate comparative data. Primary reference material has been thoroughly characterized, and it is the purest material available in quantities large enough for use. Biochemical reference standards are used for all product tests and for process-specific tests both for material release as well as for upstream/downstream process monitoring and assay development. They are unique to a specific product in its amino acid sequence and glycosylation but different for each manufacturer. To ensure compatibility with the matrix of the intended assay, different standards can be required for different process steps. It can be challenging to provide sufficient quantities of the various types of reference material early in the product development cycle [77]. A working reference material is required to validate analytical procedures [2]. It should be stable for at least 2–4 years, and its stability should be monitored regularly [77].

4.2.5.4 Change Control and Ongoing Process Validation

Validation maintenance, an ongoing activity for manufacturing processes [11], continues through the life cycle of the process with a changing focus as the process matures [20]. There is a need to address the process life cycle as a whole and not to suspend process validation after three production scale runs are completed [14]. To support this life-cycle approach, process expert teams are created to rapidly resolve process deviations, determine trends toward loss of control, comply with regulatory requirements, assess process change impact, and identify areas for process improvement [11].

A validation program is specific for a product manufactured by a given process [12]. A strong change control program needs to be established once the process is validated [15]. Changes to process equipment, operation, or facilities should be reviewed carefully before the change is approved to determine the potential valida-

tion impact and if repeating validation studies are required [12, 25]. Such changes include process improvements, raw materials changes, step substitutions, and scale-up [3]. Changes that are expected to shift the value of a performance parameter require revalidation [15]. Specifically, if the purity is decreased at a specific step, then recovery of this purity must be demonstrated downstream [15]. In general the potential quality impact of process changes is higher with glycosylated rather than with nonglycosylated proteins [13].

The process change is documented in a proposal with its justification, along with the number of batches necessary and strategy (e.g., samples and data needed, extent of validation testing, and acceptance criteria) to evaluate the change [15]. In some cases, the original risk assessment (e.g., FMEA) is revisited or a new one conducted to ensure an unintentional new failure mode has not been created [71]. A formal change control report is written and approved [15].

Revalidation is the repetition of the validation process or specific part of it [25], and it has some conceptual overlap with retrospective validation. Periodic revalidation has been conducted in some cases even if nothing has changed [25]. Specific elements of most validation programs are repeated (at least partially) at regular, appropriate intervals (e.g., every 6–24 months) to verify that the original parameters are still effective [3, 12]. In other cases, if there have been no changes, process revalidation can consist of a formal review of operating and performance parameters, along with the nature and frequency of excursions, which can be executed as part of the annual product review [15]. When existing processes are reassessed, some input parameters may be more tightly controlled than previously permitted or a noncritical parameter may be found to be critical [32]. Product failures occurring within validated ranges of a process might be due to simultaneous excursions of several variables not studied during the initial process validation or from the use of an inadequate scale-down model [20].

Trending of process variables is used to refine range limits [3]. Manufacturing data can lead to superseded NORs and/or MORs, which are justified by the associated operational trends and product quality achieved [20]. Extreme parameter values subsequently can become acceptable in process validation if the acceptability of final product has been confirmed by multiple observations [12].

4.2.5.5 Process Validation Documentation

Documentation of process validation serves to establish that its goals are reasonable and achievable, as well as to ensure that the study design is based on solid scientific and engineering principles [12]. The process validation master plan defines the scope and rationale of process validation, giving an overview of the validation, its philosophy, and general testing strategy [33]. It describes how the validation is to be done, including the schedule, studies to be performed, systems to be validated, responsibilities, and approvals required [3, 15, 33].

The process validation protocol is a preapproved written plan stating how the validation will be conducted and identifying acceptance criteria as well as sampling and assay requirements [33] and other testing details [3]. It is a prospective experimental plan that when executed produces documented evidence that the system has been validated [25]. The protocol defines the system to be validated, identifies operating variables and probable control parameters, and indicates the number of

replications required to provide statistical significance [25]. There is a major savings of cost and time realized by adopting potential streamlining measures, for example, combining resin reuse and chromatography step characterization studies into a single protocol [61]. The entire process validation study protocol is reviewed and approved by manufacturing and quality personnel [12] as well as by process development representatives. The process validation report includes the validation protocol, deviations from protocol, validation results, and conclusions about validation status of the step [3]. Copies of most critical validation reports and summaries of other reports are included in the license application [3], so their careful assembly, clarity, and accuracy is critical. Common validation submission deficiencies include the lack of data or protocols, inadequate data summaries, missing acceptance criteria, and inadequate monitoring or sampling [78].

4.2.6 PROCESS VALIDATION STRATEGIES

Several value-added, science-based, best practices are evolving for process validation, which are appropriate from both business and regulatory viewpoints. Selected industrial applications of process validation are summarized in Table 4.2-6. For a biopharmaceutical process, the potential number of variables and possible interactions among variables is large [12]. One possible approach is to conduct a worst-case test to evaluate each known critical variable separately, and if necessary to run steps more than once if they possess more than one critical variable [34]. Although the use of simple experimental designs to develop the relationship and describe the link between input and output parameters is straightforward, it can result in high numbers of experimental runs, which are impractical [10]. Potential streamlined approaches include retrospective analysis, qualified scale-down studies to identify critical parameters and important interactions, and worst-case runs [10]. In addition, more than one variable can be coupled together into a single variable if they are believed, based on science, to have a predictable effect on output variables [35]. Scouting studies then are used if process development data are limited regarding one or more variables or if the ranges previously studied were insufficiently large [20].

4.2.6.1 Historical Data Review

Retrospective analysis of historical data can be used to assess process reliability [88]. The initial process capability specifications are established based on a few runs (usually less than around 5–10) with acceptable results [30]. This number of runs often is too small to accurately define and characterize actual process variability [30, 31]. It can be difficult to claim that the previously set process capability specifications were flawed after validation runs fail to meet them [30]. Thus, the selection of acceptance criteria must consider the benefits of broad versus narrow tolerance ranges.

It is best to develop acceptance limits for parameters such as yield and purity using statistics applied to historical data [89]. The difficulty in setting acceptance criteria depends on the availability and quality of historical data. Small datasets tend to underestimate process variance because they contain only a limited number

TABLE 4.2-6. Selected Industrial Applications of Process Validation

Process Stage	Specific Description	Strategy	Reference (Company)
Fermentation	Recombinant *E. coli* protein production (defined medium, induced fed-batch process)	Bridged process changes to former process used for earlier clinical material	[38] (Amgen)
	Monoclonal NSO (GS) humanized antibody production(fed-batch process with concentrated medium additions)	Statistical DOE used random combinations of selected control parameters at high/low values in scale-down model	[79] (GlaxoWellcome)
	Recombinant yeast vaccine production (defined medium, fed-batch process)	Scale-down model to identify critical parameters	[40] (Merck)
Chromatography	Chromatography of recombinant *E. coli* protein	Parameters varied over narrow range and effect on step yield/pool purity determined	[80, 81] (Amgen)
	Reuse of column with affinity ligand for chromatography of antibody	Automation used to perform repeat cycles to evaluate elution profiles, yield, and purity	[82] (Celltech)
	Affinity chromatography of recombinant protein produced by CHO cells	Validated scale-down model used to test robustness (via fractional factorial design), reuse and virus removal	[83] (Wyeth/Genetics Institute)

TABLE 4.2-6. *Continued*

Process Stage	Specific Description	Strategy	Reference (Company)
	Chromatography steps for purification of monoclonal antibody produced by CHO cells	Scale-down studies for resin use and viral clearance fully predictive of larger scale	[26] (Genentech)
	Cation exchange chromatography of nerve growth factor produced by CHO cells	Process variables combined and linked, then statistically analyzed	[60, 84] (Genentech)
	Retroviral clearance in chromatography of antibody produced by hydrodomas	Moloney murine leukemia virus (model retrovirus) used in scaled-down chromatography column	[85] (Celltech)
	Viral reduction during manufacture of Factor IX	Scale-down models used to demonstrate log reduction.	[86] (CSL)
Overall purification	Purification of a multivalent bacterial vaccine	Matrix/family approach to reduce number of full scale validation lots from 69 to 32	[36] (Merck)
	Purification of a therapeutic monoclonal antibody	Scale-down characterization studies for various filtration and chromatography steps (including viral clearance) to predetermine acceptance criteria	[87] (Biogen Idec)

of historical production runs [89]. If historical data are used, excessively large ranges are difficult to defend.

Process variability is determined using available tools such as preparing historical trends of the mean ±3 standard deviations SDs to demonstrate agreement of manufacturing scale runs with clinical manufacturing/development runs [11]. After 15 or preferably 30 data points are obtained, a control chart based on a moving range is the best tool for monitoring process stability [89]. Statistical process control (SPC) and multivariate analysis can be applied to historical data to identify strategies for improving yield through investigation of cause-and-effect relationships using correlation tools and process knowledge [88].

4.2.6.2 Statistical Design of Experiments (DOE) and Analysis for Process Characterization

Experimental designs are used to efficiently identify those input variables that significantly affect output [20]. The use of DOE to easily screen a variety of operating parameters provides a framework for the design and interpretation of experiments, identifies those factors with the greatest effects, segregates key from nonkey parameters, identifies interactions and synergistic effects, and models how outputs relate to inputs [37, 65]. DOE is a powerful, prospective method compared with retrospective analysis [10]. Its ability to determine interactions between key parameters leads to the identification of other weak spots in the process not observed during initial screen experiments [65]. DOE is limited to assessing interactions among input parameters that can be tested within the same experiment [10]. Usually there are more variables than can be tested in single experiment, however [10]. To prepare for successful characterization via DOE, there is a need to design for simplicity by removing non-value-added experiments and to remove as much experimental variation as possible [37].

DOE modeling can be used early in process characterization to set guard bands, ranges for key process input variables where no statistical change to output is observed [31]. These guard bands are set to locate optimal settings that maximize output and minimize variation. Subsequent validation consists first of experimental design to screen key process input variables set at the guard bands previously determined and then to confirm that the output is within specification [31]. Modeling DOE helps understand the relationship between key input factors and critical Ys, relates input factors to responses (critical Ys) via a model (transfer function) that essentially is process characterization, determines input factor settings that optimize responses, and uses a model to set a limit on input variation such that no statistical changes in KPIVs are observed [37]. This approach is consistent with the PAT initiative.

The maximum information per experiment can be obtained by combining studies and varying factors (i.e., variables) using fractional factorial design [61]. A set of fractional factorial runs provides an estimate of each variable's effect and interactions, but no single run can be compared with a control run [35]. This design permits a large number of variables to be tested with lower number of experiments. Often variables are tested at a low and a high level that permits only linear interpolation (i.e., assumes a linear process response) [35]. If center points (i.e., midpoint of the tested range) are added to the experimental design, nonlinearity or

curvature can be detected if present. Replication of low- and high-level test conditions increases the precision of the estimate of that factor's effect. Two-way variable interactions are tested with factorial design, but additional experiments may be necessary to deconvolute the effects of two factors that are confounded (i.e., indistinguishable effects from one another). Fractional fac-torial designs test the extremes of all variables and then generate the best-fit model with an evaluation of the statistical confidence of the model response predictions. If no process failures are predicted by the best-fit model, then the process step is considered robust over the ranges of control parameters tested [35].

Statistical analysis demonstrates which input parameters are important contributors to output parameters [10]. JMP statistical software (SAS, Cary, NC) can be used to analyze data and generate separate analyses for each response variable of interest [61]. A difference of 3 SDs often is selected as the criterion for significance corresponding to a 95% confidence level [61], and the test acceptance criteria range typically are set as the mean plus/minus 3 SDs (industry standard) [91].

4.2.6.3 Family/Matrix Validation and Platform Technologies

Common validation studies are required across different processes to demonstrate capabilities for viral clearance, resin and membrane reuse/sanitization/storage, buffer stability, filter extractables, and resin leachables [14]. Furthermore, many biopharmaceuticals are being developed using common platform technologies (e.g., cell line, medium, unit operations) to reduce development time [7]. Thus, templates can be developed that identify key input and output parameters for a certain unit operation and then customized to address unique process or product specifics [14]. Generic validated assays can be used for impurity removal, if a platform cell line and similar culture conditions are used that then are qualified for each new product [14]. In addition, generic validation can be developed in which the supplier and potential industry users define generic operating conditions under which the technology is to be used, and the equipment manufacturer conducts much of the testing for every industry user [90]. This reduces additional user validation testing to only product- or user-specific applications (e.g., product compatibility) [90].

To significantly reduce the number and extent of new studies associated with new products processed using similar or identical process operations (i.e., platform technologies), family and matrix validation approaches are applied to reduce repetitive work [33]. In a family approach, one piece of equipment is validated by three consecutive runs and other similar equipment is validated by one confirming run in each unit [33]. This approach can be applied to the process validation for a product with several distinct, different but similar, components (e.g., antigens for a multivalent vaccine) by (1) treating different product components as a product family, (2) classifying product components into groups based on their similarities, and (3) selecting one component from each group to validate, possibly based on worst-case experience during process development [36]. This strategy is facilitated when (1) the final product can be fully analytically characterized, (2) there is significant prior manufacturing experience with similar production processes and significant process development experience with the new production process, and (3) clinical trial data show comparable safety and efficacy profiles for some product components [36].

In a matrix approach, validation is conducted at the full range or extremes of process parameters, and then values in between are assumed validated [33]. This generic strategy is used to support a wide range of bracketed conditions that include the most common operating parameters for more than one product, as long as process streams and key step components (e.g., resin type) are similar [14, 91]. The matrix approach reduces the extent of process validation required for successive products, at the expense of only a limited impact on the initial product's process validation, as long as the platform technology is reasonably maintained. Example applications have been retrovirus inactivation via low pH treatment [42] and viral clearance using anion exchange chromatography [91].

4.2.6.4 Scale-Down Models

Although the most reliable data are obtained from actual production runs [12], determination of operational ranges at the manufacturing scale is laborious, time-consuming, and costly [40]. Thus, typical manufacturing scale validation is limited to impurity clearance (e.g., proteins, DNA, and small molecules) and resin/membrane cleaning [14]. If the process step cannot be scaled down successfully, then range definition validation studies are required at the large scale [32].

Small-scale process models are an essential and valuable tool for process validation and ongoing troubleshooting [32]. Scale-down factors ranging from 10- to 10,000-fold are employed [3] with the extent of scale-down de-pending on the actual production scale and smallest scale that can reliably reproduce the process [51]. Small-scale equipment is permissible only if the scalability of the unit operation is demonstrated [12]. The same technical principles for scale-down are used as for scale-up for the step of interest [3].

The scale-down model should represent the large-scale model with respect to input parameters and typical values for output parameters [10]. Data are collected under conditions relevant to full-scale manufacturing GMP process [12]. Qualified scale-down models are used in combination with strong statistical tools like DOE [10], but sample handling at the small scale is easier than during GMP manufacturing runs [26]. Multiple validation experiments can be conducted in parallel employing several identical scale-down units, thereby shortening the experimental time expended [3]. Also a hybrid approach can be instituted where samples from full-scale process streams are used as feed streams to scaled-down steps [3]. Overall the amount of re-sources used in small-scale validation is likely to be less than that needed for manufacturing scale validation, although in manufacturing scale validation, resource utilization is spread over a longer period of time [26].

Scale-down studies have been used for a wide variety of process validation studies, including resin lifetimes, in-process stream hold times, buffer stability, virus clearance, harvest criteria, filter extractables, resin leachables, and cell age at harvest [14, 91, 92]. The ease of scale-down differs depending on step and should be considered in selecting those steps to be validated [5]. In fact, certain validation issues can be addressed only via small-scale models (e.g., virus clearance evaluation, nucleic acid and other impurities/additives removal, cleaning and storage procedure evaluation, and column lifetime estimation) because their use increases worker safety, reduces costs, and permits use of higher titer samples for improved

accuracy of prediction [52]. Specifically, viral clearance studies can only be performed at the small scale because virus introduction into cGMP manufacturing scale equipment is impractical and inappropriate [5, 26]. For viral clearance studies, the ideal scale-down factor is 10- to 100-fold [6].

Although scale-down models have been used largely in purification, they also have been used in fermentation. Fermenter scale-down models use the same set points for volume-independent operating parameters (e.g., temperature, pH, and DO) and adjust the set points for volume-dependent parameters such as mixing and gassing (e.g., dCO_2 stripping) [68]. The inoculum split ratio for cell culture scale-down is maintained constant [3, 68]. Characterization studies are performed in small-scale fermenters, and then it is demonstrated that the ranges established are insensitive to scale-up [40]. Only the critical process parameters found to be sensitive to scale-up require range studies at the manufacturing scale [40].

There is increased regulatory concern over the accuracy of results obtained from small-scale models [52]. Consequently, the scale-down model must be validated to be consistent with full-scale manufacturing before validation studies begin. For chromatography steps, it is necessary to determine that product purity and yield are the same [52] or demonstrate comparable HETP, peak asymmetry, and retention time [5]. Any product streams tested should be representative of a commercial-scale process feed stream [52].

For chromatography steps, the scale-down model consists of a column with system and auxiliary components (e.g., distributor, monitors, and fraction collectors) [52]. Scale equivalence for chromatography columns maintains constant column bed height and linear flow rate, while varying column diameter, buffer, and load amounts, which are scaled to column volume [61]. Specifically, the column diameter is decreased, but the bed height is maintained to maintain residence time, and the volumetric flow rate is reduced, but the linear flow rate is maintained [5, 52]. Constant residence time is important if viral clearance is due to inactivation rather than removal [52]. Configuration, transport distances (tubing diameters as well as tubing lengths), and materials of construction are similar to the commercial-scale system. The same methods of preparing buffers are used, including the same quality of water, buffer, and salts. The chromatography medium has the same base matrix, functional groups, and degree of substitution, as well as the lot used should meet approved specifications [52]. Finally, the product mass loading and relative buffer/load volumes between scale-down and production systems are similar [33].

Although chromatography scale-down is extensively studied owing to its use for viral clearance validation, the scale-down of other purification steps also is conducted. Virus filtration scale-down maintains the same linear or filtration pressures, product feed concentration, ratio of feed volume to filter area, and temperature as the production system [33]. Other steps such as solution inactivation (e.g., pH and heat treatment) are relatively easy to scale down because it is simply necessary only to maintain buffer composition, pH, protein concentration, and temperature consistent with production conditions [5]. The time course of the inactivation is quantified along with the upper tolerable range of inactivation agent concentration and minimum exposure time. Residence time differences between the production and small scales might change parameters such as buffer tempera-

ture [52], which might affect solution as well as chromatography inactivation steps.

4.2.6.5 Well-Characterized Biotechnology Products

A well-characterized biological (biopharmaceutical) is a chemical entity whose identity purity, impurity, safety, potency, and quality can be determined and controlled [19, 93]. To be well characterized, the drug substance must be >95% of the main component and/or related isoforms [93]. Well-characterized molecules are evaluating using sensitive and discriminating tests that are quantitative and relevant *in vivo* and *in vitro* potency assays [93]. The recent explosion in the availability of sophisticated, reliable, analytical instrumentation, combined with extensive, sensitive product analysis methods has resulted in great advancements in defining "well-characterized" biopharmaceuticals [28].

Although for a well-characterized biological the FDA trend is to rely on reduced final product testing, process validation must be present to assure product quality and consistency [15]. There has been an elimination of regulatory agency lot release for specific well-characterized biopharmaceuticals [19, 93]. In addition, process-related impurities (e.g., host cell protein and DNA) are controlled by process validation *in lieu* of lot-release testing [27]. Furthermore, many process changes are justifiable using analytical data and process validation studies without a clinical trial [3]. The following principles can be applied to the manufacturing and testing of a well-characterized product: (1) The manufacturing process should be robust, reproducible, validated, and designed to produce active drug substance; (2) the safety of the final product is assured through process validation using validated analytical testing to demonstrate removal of impurities to safe levels; (3) tests for identity, purity, and potency should be sensitive, quantitative, and validated; and (4) specifications should be quantitative and based on historical manufacturing data and clinical experience [27].

The more characterizable the biopharmaceutical product, the more emphasis is placed on validating that the correct molecule is being produced than assuring that the cell biology is being controlled [10]. However, the difficulty of characterization increases in direct proportion to the complexity of molecule [93]. When less is known about the product, a greater reliance is placed on product and process consistency [10]. Most vaccines used today are not well-characterized biologicals, so batch release must be performed by the manufacturer and by the appropriate national control laboratory [19]. The quality of vaccines is increasingly guaranteed by the use of robust and reproducible production processes [19], and thus, a high reliance is placed on process validation.

4.2.7 FUTURE TRENDS

Future developments in the biopharmaceutical industry are likely to impact the scope and execution of process validation activities. The nature of process validation is continuously changing to meet the requirements of biopharmaceutical development and manufacturing. The understanding and implementation of new strategies based on future developments is key to maintaining an effective process validation methodology.

4.2.7.1 Process Analytical Technologies (PATs)

PAT is a system for designing, analyzing, and controlling manufacturing through timely in-process measurements of critical quality and performance attributes, leading to the goal of ensuring final product quality [94]. The implementation of PAT potentially minimizes the number of tests that need to be performed at the time of lot release, or in the future for certain products, it might eliminate lot-release testing by the manufacturer entirely. Its precedent was the dropping of lot-release testing for certain impurities when validation of their removal was able to be assured [94].

Online and automatic methods have been demonstrated to be more accurate and precise compared with manual methods because (1) sampling and sample pretreatment artifacts are eliminated, minimized, or reproduced; (2) measurement frequency is increased; and (3) results are independent of personnel availability [69]. Continuous, real-time monitoring is preferred when feasible [11]. PAT is used to implement in-line controls to increase productivity and reduce costs [31]. In addition, accumulated data from numerous commercial batches are used to generate trend analysis profiles showing high and low control limits for process parameters [25]. These limits then are used to predict when processes may be deviating from their validated control ranges, although they are currently operating within them [15].

Relationships among manipulated (controlled) variables, online measured variables, and product (uncontrolled) variables in most biosystems are nonlinear to some extent [95]. A forward model is when parameters, starting conditions, and relevant equations governing behavior are known, readily measurable inputs and the outputs are variables; an inverse model is when the inputs are readily measurable variables and the outputs are difficult to measure parameters [69]. The forward model is most applicable to process validation, whereas the inverse model is most applicable to metabolic pathway analysis. Modeling systems such as neural networks have been used to describe the characteristics of extremely complex bioprocess systems [95].

Mathematical models can be used to simulate the controlled process variables and thus predict the effect of variations on the uncontrolled process variables [35]. Linking online sensing to modeling is effective when (1) there is product yield and biomass variation among optimal values, (3) optimal values may vary over time for processes that are not stationary, (4) parameters can be measured directly or otherwise, (5) the cost of online control is a small fraction of capital and expense costs to run a process, and (5) historical data combined with mathematical methods provide identification of key parameters and their optimal values to achieve rational process improvement [69]. Achieving good modeling is not always easy and involves correct identification of parameters and variables, and selection of the type of model (forward or inverse) along with key inputs and outputs, showing the relationship between predictions and actual data to assess model effectiveness [69].

A solid understanding of a product's critical quality attributes and what aspects of the manufacturing process control them is necessary to fully gain the benefits of PAT [94]. Furthermore, the inherent complexity of protein-based biopharmaceutical products makes it difficult to use PAT to assess product characteristics critical to safety, efficacy, and stability. In addition, it is difficult, compared with

small molecules, to directly monitor the desired product concentration during upstream/early downstream processes in a background of protein impurities deriving from medium components or host cells [94]. However, PAT can be used for process monitoring and control that then indirectly results in improved productivity, process consistency, and product quality.

The pharmaceutical industry lags behind other automated industries in manufacturing quality analysis because it is mostly lab-oriented with little closed-loop, real-time control, and limited enterprise-wide data availability [96]. There is a fear of potential regulatory agency reprisals if PAT is implemented for existing processes, and its use detects behavior that would not have been detected using conventional process monitoring [96]. Before PAT is widely implemented, the risks associated with data variability need to be evaluated and reliable methods need to be instituted to distinguish among signal, process, and product variability [94].

4.2.7.2 Process Reliability

More increasingly, the supply capability of a commercial organization depends not only on manufacturing but also on process reliability, GMP compliance, and operational metrics [79]. Process reliability lies at the heart of lean manufacturing and Six Sigma programs because it ensures that the manufacturing process can be maintained in a compliant, validated state [97]. Performance factors are measured and monitored on an ongoing basis so that improvement efforts can be targeted at the most significant opportunities leading to the removal of variation from the manufacturing process [97]. The greatest threats to process reliability are production variances and associated investigations [79]. Variance analysis identifies systems prone to problems, and then it uncovers the root causes of these variances, strengthening the mechanical and operational aspects of the process [79].

Process reliability is the ability of the process to consistently produce required results as measured through the primary dimensions of uptime, dependability, and first run yield [97]. Uptime is the time the process is in operation compared with the available time the process is scheduled to be in operation. Dependability is the repeatability of a process' actual run rate compared with its scheduled run rate. First run yield is the ability to produce quality outputs the first time through production run without any rework. Reliability losses are measured in terms of unscheduled downtime, run rate losses, yield losses, and reprocessing [97].

Process reliability is improved most effectively using cross-functional teams by the following process: (1) identification of the opportunity; (2) collection of reliability loss data regarding uptime, dependability, and first run yield; (3) analysis of loss data and determination of the root cause of the problem; (4) brainstorming of solution alternatives; (5) selection and implementation of solutions considering solutions that are safe, feasible, implementable, and cost-effective; and (6) monitoring of results and repetitions to assess the impact of solutions and to prioritize remaining opportunities [97]. Six Sigma states these concepts for continuous process improvement as DMAIC: define, measure, analyze, improve, and control [37], which are readily applicable to process validation. Measurable benefits of improved process reliability include increased customer service (e.g., timely delivery), increased schedule adherence, reduced lead time, reduced inventory levels, increased effective capacity (i.e., greater process uptime and reduced unplanned

downtime), decreased cost, creation of time available for predictive maintenance, incremental capacity for new products or increased volume without additional capital investment, increased process dependability, improved quality and first run yield, and reductions in setup and changeover time [97].

Process flexibility is needed for rapid turnover and reduced inventories that are key to lean manufacturing, which in turn are crucial to making more customized drug products and remaining competitive [97]. Flexibility losses are when time, people, and material waste are consumed by product changeovers. Flexibility is improved by mapping the changeover process, analyzing steps, and then eliminating, resequencing, or improving activities. In addition, standardizing procedures and setup locations and advance preparation for changeovers improve efficiency [97].

4.2.7.3 Biogenerics

Biogenerics, also known as "follow-on" biologics [98], are pharmaceutical preparations, using a generic name, that are based on drug substances arising from recombinant technology (complex structure and high molecular weight) that have been demonstrated to be essentially similar to an original pharmaceutical with an expired patent [99]. The main features of biogenerics processes (such as reproducibility, validation, and controls) need to be maintained similar to the patented biopharmaceutical product and should include quality, safety, and efficacy [100]. Key scientific issues for biogenerics are product characterization, demonstration of bioequivalence, and manufacturing issues (e.g., lack of ownership or access to a contracted facility, incomplete disclosure of patented product processes, and difficulty obtaining a suitable cell line and raw materials) [100]. The process as well as the strain for biogenerics are different from those of the original product, and the impact of even small changes on biopharmaceuticals is not clear [99].

The potential world market for biogenerics has been estimated at $5.4 billion/year by 2008, assuming the evolution of a favorable regulatory environment [101], compared with a total biopharmaceutical market of $30 billion/year [99]. These estimates may be too high for the market potential for biogenerics because patients often are switched to the next-generation versions of branded products due to rapid innovations in these products [101]. In fact, the main barriers to entry are the fast pace of existing product enhancement or new product introduction, and an ill-defined regulatory framework [99]. In addition, due to the expense of biomanufacturing and developing a biomanufacturing process, the cost reduction of biogenerics may not be as significant as with non-biopharmaceuticals [1]. One estimate is that biogenerics will sell for 10–20% less than branded counterparts rather than 40–80% less as with small-molecule drugs [101].

Generic biopharmaceutical products, possessing a similar complex structure and high molecular weight as the original product, are harder to characterize than small-molecule generic drugs; thus, they are harder to prove equivalent [101]. To show bioequivalence, that the biogeneric is "essentially similar" to the patented biopharmaceutical, sophisticated analytical analysis is required. Comparability studies are required to prove the similar nature of the generic product, and the nature of these studies is product-class specific [101]. Prior experience is that even small changes in the product can result in significant safety or efficacy differences.

Biogenerics are currently in a state of "regulatory purgatory" [98]. Key regulatory issues are that the approval process is not well defined and is uncertain, particularly in the United States [100]. The FDA says creating a regulatory pathway for biogenerics is a top priority (Europe already has a biogenerics regulatory framework), but little resolution has been reached [98].

Regulatory authorities are requesting extensive demonstrations of biological activity, which translate to lengthy and costly clinical trials [99]. Proof of identity is difficult for biopharmaceuticals because they are difficult to analytically characterize. "The process defines the product" notion still exists when there is limited knowledge [100] and experience regarding cause-and-effect relationships [99]. Extensive oversight of biogenerics manufacturers is expected because the entire manufacturing process is as important as the final product and needs to be carefully regulated [1]. These requirements make development timelines and costs substantially higher than for small-molecule generics [99].

4.2.7.4 Outsourcing

As biopharmaceutical companies redefine their goals and priorities, outsourcing of workload can maximize investment [28] and assure an ability to meet capacity demands [102]. Previously, outsourcing has been done in clinical research development and fill/finish manufacturing steps [28, 103]. Now it is being done for QC/QA functions because every quality function except final release responsibility for biopharmaceutical drug product for human clinical trials can be outsourced [28]. Outsourcing also is occurring in many areas such as process development, clinical material production, and marketable production [102, 104]. Specific areas such as cell line development (high producer screening) and scale-up also can be outsourced [104]. Risk management systems are used to proactively identify the risks and liability between the organizations [105].

Contract companies can provide more than simply additional capacity. They can provide translation of bench-scale operations to cGMP compliant manufacturing, technology transfer, and process validation [104]. Contract services also are provided by equipment suppliers to optimize/develop processes using their equipment [90]. These services can be more cost-effective than third-party laboratories, contract manufacturing, or in-house.

4.2.7.5 Risk-Based GMPs

In the future, when manufacturing processes are developed and understood, there will be increased innovation and regulatory oversight proportional to risk [23]. The major goals of risk-based GMPs are to focus GMP attention on potential risk areas, ensure regulations do not impede innovations, enhance GMP inspection consistency, and encourage the use of the latest scientific advances in manufacturing [106]. To accomplish these goals, work is pro-gressing based on several major principles, including risk-based orientation, science-based policies/standards, integrated quality systems orientation, international cooperation, and strong public health protection. The advent of risk-based GMPs provides a timely opportunity for industry to prospectively evaluate ways to streamline the complexity of existing and proposed processes using sound and defendable methodologies for risk assessment [106].

4.2.8 SUMMARY

Overall, process validation is a methodology to permit organizations to take advantage of process improvement opportunities presenting themselves over the course of a product's lifetime. Process validation continues to be a formidable undertaking, requiring extensive resources and time for full execution. Improvements in efficiency are likely to arise as technologies for high-throughput scale-down units and fast-turnaround, sensitive analytical assays become more readily available. Focused guidance on process development, characterization, and validation also should be beneficial to evaluate and align varied industry practices.

NOMENCLATURE

API—active pharmaceutical ingredient
BSE—bovine spongiform encephalopathy
CBER—Center for Biologics Evaluation and Research, US FDA
CCP—critical control points
CQA—critical quality attributes
CDER—Center for Drug Evaluation and Research, US FDA
CV—coefficient of variation
DO—dissolved oxygen
dCO2—dissolved carbon dioxide
DOE—design of experiments
EMEA—European Medicines Evaluation Agency
EU—European Union
FDA—(United States) Food and Drug Administration
FME(C)A—failure mode and (critical) effect analysis
FTA—fault tree analysis
(c)GMP—(current) Good Manufacturing Practice
HACCP—Hazard analysis and critical control point
ICH—International Conference on Harmonization
KPIV—key process input variables
LAL—limulus-amoebocytes-lysate
LOD—limit of detection
LOQ—limit of quantitation
MOR—maximum operating range
NOR—normal operating range
PAR—proven acceptable range
PAT—process analytical technology
PCR—polymerase chain reaction
PDA—Parenteral Drug Association
POD—probability of detection
PV—process validation

QA—Quality Assurance
QC—Quality Control
RPN—risk priority number
SD(s)—standard deviation(s)
SOP(s)—standard operating procedure(s)
SPC—statistical process control
TOC—total organic carbon
WHO—World Heath Organization

A drug must be formulated in a safe, consistent, and stable dosage form with proven clinical efficacy before it can be approved for specific therapeutic indications by drug regulatory authorities. Although biotechnological/biological products or biopharmaceuticals (therapeutic proteins, peptides, and nucleic acids) are no exception to this requirement, the inherently complex primary structures of this important class of therapeutic agents coupled with their ability to form higher order structures have posed additional challenges and constraints in their formulation and assessment.

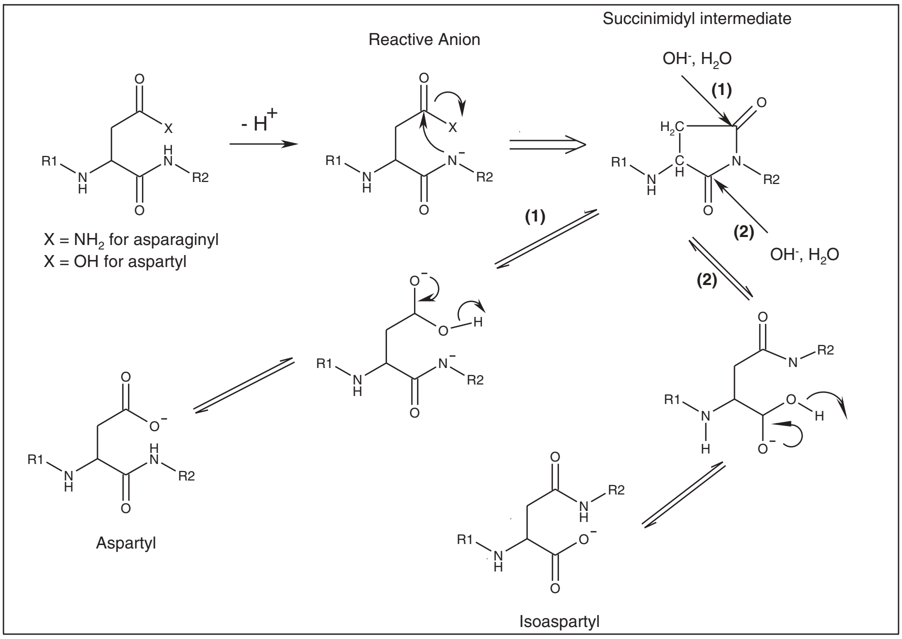
The current chapter is intended to provide an overview of the stability problems of biopharmaceuticals and their assessment as well as the formulation approaches that can be used to circumvent these problems. Presented next is a literature review on the known degradation/denaturation mechanisms of various biopharmaceuticals, followed by a general discussion on the formulation strategies using specific excipients/additives for improving the product shelf-life.

4.3.1 CHEMICAL INSTABILITY AND POTENTIAL DEGRADATION PATHWAYS

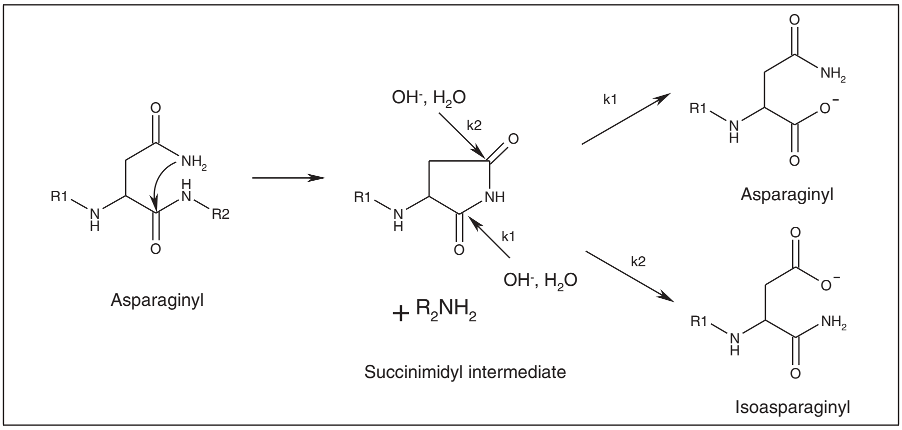
4.3.1.1 Hydrolytic Reactions in Proteins and Peptides

Deamidation. Deamidation is a common degradation pathway for proteins and peptides, involving the conversion of the side chains of the asparagine and glutamine residues to the respective carboxylates of aspartate and glutamate. The reaction is highly pH dependent. Under acidic conditions, the reaction is initiated by the direct intermolecular attack of water at the side-chain amide linkage, yielding ammonia and the corresponding acids (i.e., aspartic acid for asparagine residue or glutamic acid for glutamine residue) [1–3]. At neutral or basic pH, the degradation is predominated by intramolecular deamidation with a relatively minor contribution from direct hydrolysis [2].

Mechanistically, deamidation of asparagine proceeds via the formation of a succinimide intermediate, involving the intramolecular attack by the nitrogen in the peptide bond on the C-terminus (Scheme 4.3-1) [2, 4]. The resulting cyclicimide tends to racemize at α-carbon. Hydrolysis of the cyclicimide yields a mixture of peptide products differing in the type of amide linkage in the polypeptide backbone; for the α-carboxyl linkage, the hydrolytic products are a mixture of *d*- and *l*-normal aspartyl peptides, whereas the β-carboxyl linkage affords a mixture of *d*- and *l*-isoaspartyl transpeptidation products [3, 5]. Spontaneous deamidation of the polypeptide chain at the asparagine residue can also occur via the attack by the



Scheme 4.3-1.



Scheme 4.3-2.

nitrogen in the side chain of the amide on the following peptide-bond carbonyl to form two polypeptides, one of which contains a C-terminal succinimide residue (Scheme 4.3-2) [3]. Most biopharmaceuticals are formulated at physiological pH (7.4) for parenteral administration and thus are prone to decomposition by deamidation via the aforementioned mechanisms. These products encompass recombinant human parathyroid hormone [6], orthoclone OKT3 [7], human epidermal growth factor [8], insulin [9], antiflammin 2 [10], recombinant tissue plasminogen activator [11], monoclonal immunoglobulin h1B4 [12], and murine monoclonal antibody MMA383 [13]. Adenovirus, a therapeutic viral gene carrier, is also known

to degrade by deamidation and isoaspartate formation at four susceptible asparagine residues, and the stability of a recombinant adenovirus AV3760 has demonstrated considerable improvement after site-directed mutagenesis of the key asparagine residues in the hexon protein [14].

Similar to the asparagine residue (Scheme 4.3-1), glutamine residue undergoes deamidation at neutral or alkaline pH, where intramolecular attack results in glutarimide formation. Having one more methylene group than the asparagine residue, the glutamine residue yields a six-membered ring intermediate structure, which is formed at a much slower rate than that of the five-membered succinimide intermediate for the asparagine residue because of entropic factors [1, 11]. Although the asparagine residue is widely known to be more susceptible to deamidation than the glutamine residue, more facile deamidation for the glutamine residue under acidic conditions has been observed with the glucagon fragment 22–29 [15]. The lower reactivity of the asparagine residue in this case has been attributed to a decreased electrophilicity of its side-chain carbonyl carbon imparted by a parallel cleavage pathway at this residue.

Primary sequence has an important bearing on the spontaneous deamidation in peptides. It has been demonstrated using model peptides that the structure of amino acid residue immediately following the asparagine residue N + 1 exerts a significant impact on the overall rate of succinimide formation. For example, glycine residue in the N + 1 position results in a deamidation rate 70- to 100-fold faster than that found for amino acid residues with branched hydrophobic side chains [2]. In another study, the bulky side chain of N + 1 histidine residue has been found to limit the flexibility of the model peptide around the reaction site, thereby reducing the reaction rate [3]. As isoaspartate formation depends on both primary sequence and chain flexibility, two important generalizations can be made [11]. First, isoaspartate tends to form preferentially at the asparagine-glycine, asparagine-serine, aspartic acid-glycine, and possibly asparagine-histidine sites. Second, isoaspartate formation is favored in the highly flexible region of a polypeptide chain. However, it must be noted that these generalizations, which are based on solution-state data, may not be applicable to solid peptides because the mechanisms of deamidation involved in the solution and solid states are intrinsically different. As has been demonstrated in the solution state, a glutamine residue in the N + 1 position can either hinder asparagine deamidation by electrostatic and inductive effects or enhance the reaction though general acid/base catalysis, whereas in the solid form, a glutamine residue in the N + 1 position can increase the hydration of the peptide and afford asparagine deamidation rates similar to those in solution [16].

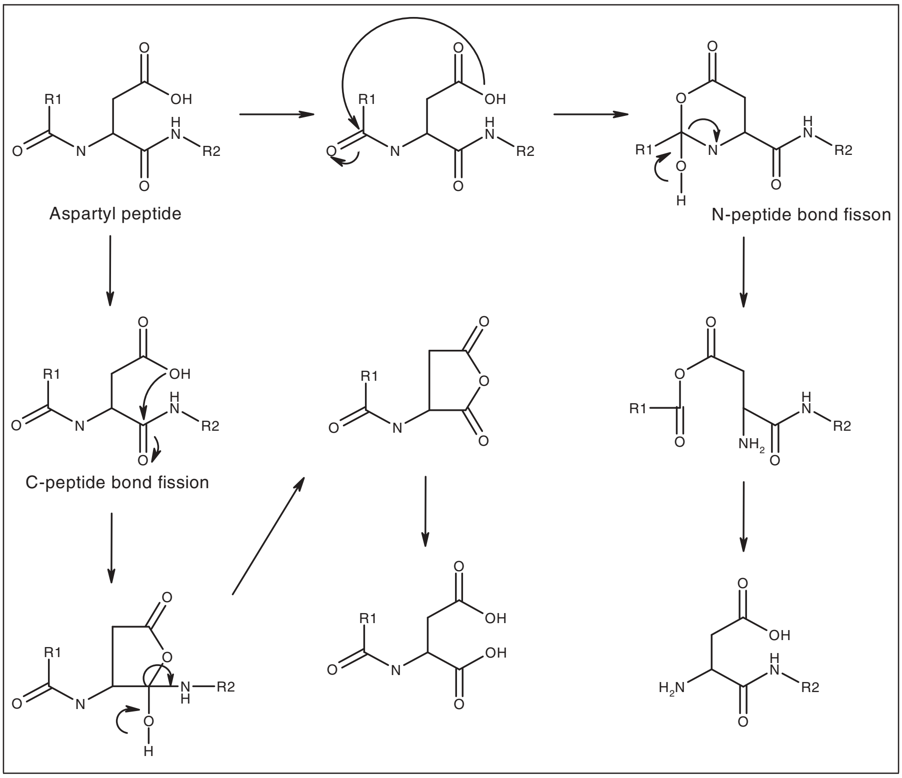
Higher order structures, viz. secondary, tertiary, and quaternary structures, also influence deamidation in proteins by positioning the asparagine or glutamine residue in spatial proximity to a functional group elsewhere in the primary sequence, which is capable of accelerating or inhibiting the deamidation. In addition, the conformational structure of the asparagine or glutamine residue and the nearby peptide region containing it may be strongly conditioned by the nature of the structural environment that incorporates the residue [17]. In general, α-helices, β-turns, and possibly β-sheets can stabilize asparagine residues against deamidation and drastically reduce the rate of succinimide formation for a given sequence relative to the same sequence in a random coil [11]. However, the effect is relatively weak with α-helices and destabilization of the asparagine residues may even occur

[17]. Conformational restrictions and reduced nucleophilic reactivity of the backbone NH centers have been suggested as probable stabilizing mechanisms with the higher order structures. In recombinant human lymphotoxin, asparagine deamidation can be inhibited by secondary and tertiary structures due to reduced polypeptide flexibility [18].

Apart from protein sequence and structure, temperature, pH, and the type of buffers can all influence the deamidation and isoaspartate formation. The effect of temperature on the deamidation reaction rate generally follows the Arrhenius law. Deamidation activation energies around 21~22 kcal mol^{-1} have been reported for two model peptides under alkaline conditions [19, 20]. The deamidation is also subject to general acid/base catalysis, as evidenced by an increase in deamidation rate with an increase in buffer concentration [2].

In stability assessment, chromatographic methods of high sensitivity are normally required to analyze the degradation products formed from parent drugs in trace amounts. Biological potency is not a sensitive marker for detecting deamidation and isoaspartate formation, which may or may not influence the biological activities of protein and peptides. If the asparagine and glutamine residues are not involved in receptor binding, there may not be any effect on biological activity upon deamidation, as in the case of human growth hormone [21], insulin [22, 23], recombinant human flial cell line derived neurotrophic factor [24], interleukin-1α [25], and recombinant human interleukin-2 [26]. However, activity loss associated with deamidation is probably the norm rather than the exception, particularly if the asparagine or glutamine residues take part in receptor binding, as exemplified by calmodulin, CD4, human and murine epidermal growth factors, growth hormone releasing factor, methionyl murine interleukin-1β, parathyroid hormone, and bovine pancreatic ribonucleases A [25]. It is important to note that in addition to the direct effect of receptor binding on activity, modification of a site outside the binding region may affect the biological activity indirectly through a local conformational change, and isoaspartate formation can also elicit autoimmunity against the proteins/peptides [11].

Peptide Bond Cleavage at Aspartic Acid Residues. The breakdown of proteins and peptides may occur by cleavage at the amide bonds. Although all amide bonds are theoretically susceptible to hydrolysis, they normally exhibit different hydrolytic rates. For instance, the rate of acid-catalyzed hydrolysis in polypeptides containing the aspartic acid residues are at least 100 times higher than those of the other peptide bonds [3, 4, 27]. The cleavage proceeds via either the *N*- or *C*-terminal bond adjacent to the aspartic acid residue (Scheme 4.3-3) [4]. For example, in acidic solutions, antiflammin 2 undergoes both *C*- and *N*-terminal hydrolyses across the aspartyl peptide bonds, and the peptide bonds at C-termini of the aspartyl residues are most susceptible to hydrolysis [28]. In addition, isoaspartate formation with aspartic acid residue is possible via the cyclicimide intermediate, as shown in Schemes 4.3-1 and 4.3-2. The influence of primary sequence on aspartic acid degradation is significant, but probably not as obvious as that observed for the asparagine residue deamidation [3]. The N + 1 glycine, which confers the greatest flexibility on the polypeptide chain, has been shown to be most vulnerable to hydrolysis at the aspartic acid residue in model peptides, which are structurally analogous to adrenocorticotrophin fragment 22–27 [29]. In a similar series of



Scheme 4.3-3.

hexapeptides, it has been observed that the rate of hydrolysis decreases with an increase in steric hindrance of the N + 1 residue [30].

It is well established that aspartic acid-proline peptide bonds are particularly labile and undergo hydrolysis under conditions where other aspartic acid peptide bonds are stable, e.g., at low pHs [4, 31]. The hydrolysis proceeds via intramolecular catalysis by carboxylate anion displacement of the protonated nitrogen of the peptide bond [31]. This mechanism has been demonstrated for recombinant human interleukin 11, which undergoes peptide cleavage specifically at aspartic acid[133]-proline[134] residues in acidic solution [32]. The increase in reaction rate, by approximately 8- to 20-fold, may be ascribed to the weakened amide bond resulting from the increased electronegativity of the protonated proline nitrogen [4, 27].

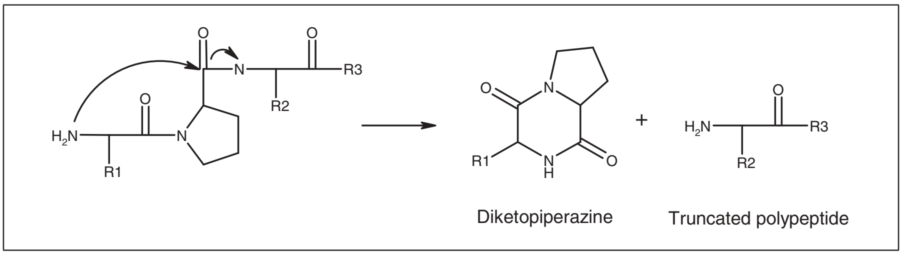
As with aspartic acid containing amide bonds, peptide bonds carrying serine or threonine are generally more labile than other amide bonds. The degradation involves the nucleophilic attack of the serine or threonine hydroxyl group on the neighboring amide bond via the formation of a cyclic tetrahedral intermediate [27]. This mechanism exhibits predominance in luteinizing hormone-releasing hormone antagonist RS-26306 at pH ~5 [33].

It is worth noting that hydrolysis of the peptide bond can also occur with other amino acids. For example, salmon calcitonin undergoes hydrolysis at the cysteine[1]-serine[2] peptide bond where the cysteine remains linked to the peptide by a disulfide bond [34].

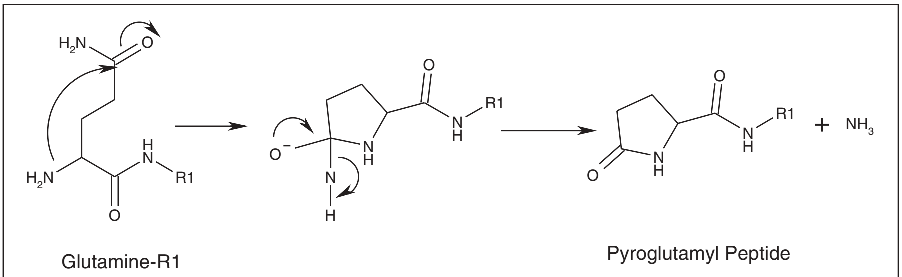
N-terminal Degradation via Diketopiperazine and Pyroglutamic Acid Formation. If the proteins and peptides possess a penultimate proline residue in an *N*-terminal sequence, the first amino acid in the primary sequence may be lysed from the polypeptide skeleton via the formation of diketopiperazine (DKP). This reaction is commonly termed nonenzymatic aminolysis, which results from the intramolecular nucleophilic attack of the *N*-terminal nitrogen on the carbonyl carbon of the peptide bond between the second and the third amino acid residues (Scheme 4.3-4) [3]. Pharmaceutical materials known to follow this degradation pathway include substance P [35], recombinant human growth hormone [36], histrelin [37], RMP-7 (a bradykinin analog) [38], as well as aspartame and aspartylphenylalanine in the solid state [39].

The rate of DKP formation generally increases with increasing temperature, as shown for RMP-7 [38] and phenylalanine-proline-*p*-nitroaniline (Phe-Pro-*p*-NA) [40]. Avoidance of general base catalysis or decreasing the buffer concentration at high pHs can minimize this cyclization reaction [38, 40]. The degree of ionization of the *N*-terminal group, which is governed by the pK_a of the amino group and the pH of the medium, also affects the rate of DKP formation because the first protonated amino acid in the sequence will not be available to effect base-catalyzed reaction. However, with Phe-Pro-*p*-NA and its analog, X-Pro-*p*-NA (where X is the other amino acid), the influence of primary sequence on the rate of DKP formation appears to be mediated through the ability of the X-Pro peptide to undergo *cis-trans* isomerization rather than through the difference in extent of ionization or in steric hindrance of the *N*-terminal amino acids [3, 40].

Pyroglutamic acid formation is a result of the condensation of either the amino group with γ–carboxylic acid group of glutamic acids or the amino group with γ–carboxamide group of glutamines at the *N*-terminal positions (Scheme 4.3-5) [27].



Scheme 4.3-4.

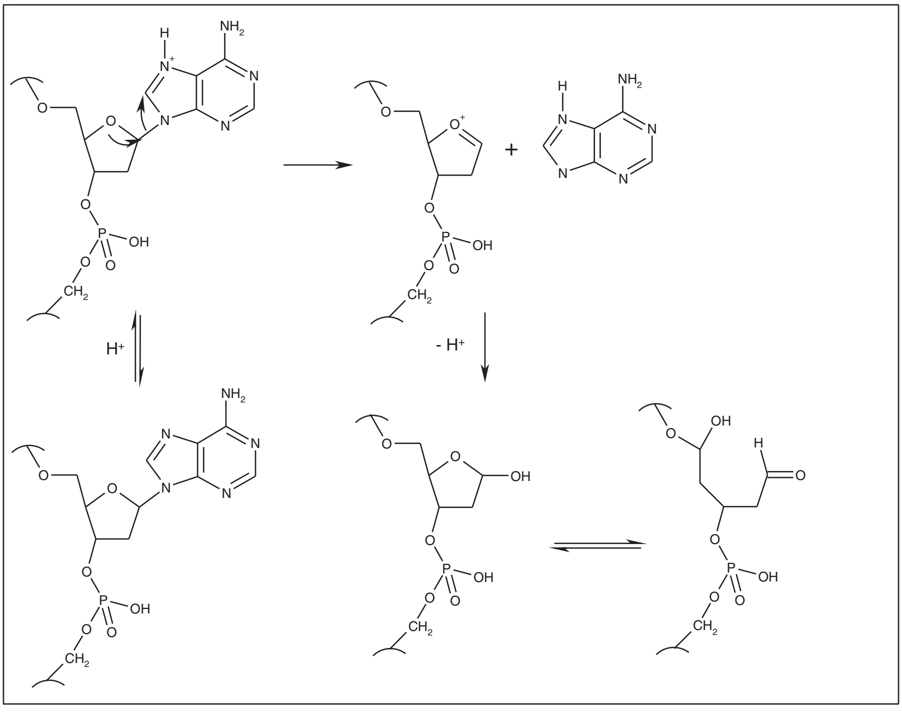


Scheme 4.3-5.

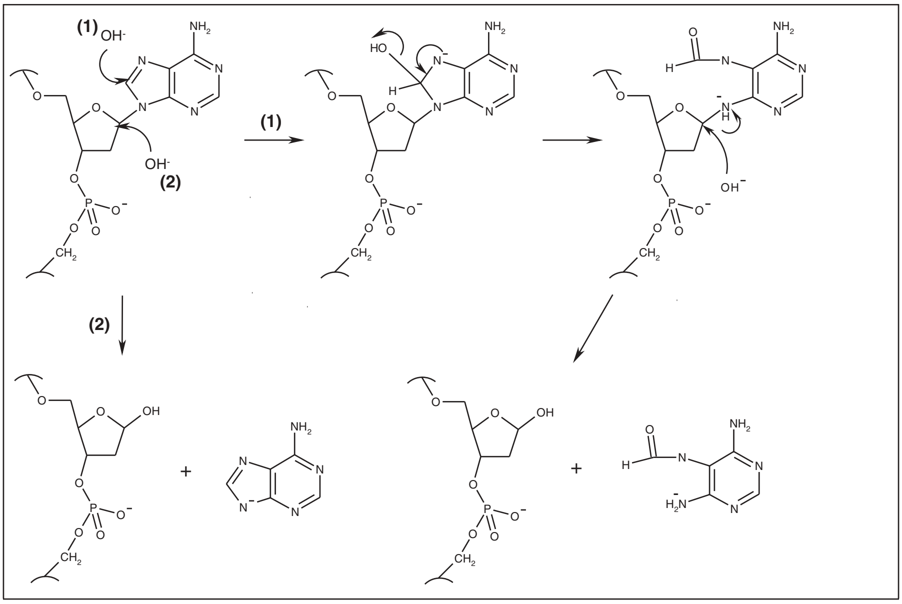
It has been shown with model peptides that the rate of pyroglutamic acid formation is the fastest when the N + 1 amino acid residue next to glutamine is asparagine, leucine, or glycine [41]. Pyroglutamic acid formation in proteins and peptides is usually accompanied by a loss of biological activity. For example, decapeptide ELA, a Melan-A/MART-1 antigen immunodominant peptide analog, exhibits reduced binding to the specific class I major histocompatibility complex and a loss of cytotoxic T-lymphocyte activity after conversion of its *N*-terminal glutamic acid to pyroglutamic acid [42]. However, several peptides of pharmaceutical interest (including buserelin and gonadorelin) have been developed with the chemically more stable pyroglutamic acid instead of N-terminal glutamine or glutamic acid without loss of pharmacological activities.

4.3.1.2 Hydrolytic Reactions in Nucleic Acids

Depurination and Depyrimidation. Depurination, which refers to the hydrolysis of the *N*-glycosidic bond, is an important degradation pathway for nuclei-acid-derived drugs. By inhibiting free radical oxidation, depurination and β-elimination (Section 4.3.1.4) represent the most significant pathways for the degradation of DNA [43]. Due to the inductive effect of the 2′-OH group, deoxyribonucleosides and deoxyribonucleotides in DNA are more susceptible to depurination than are the ribonucleosides and ribonucleotides in RNA. The hydrolysis of *N*-glycosidic bond in DNA can be acid- (Scheme 4.3-6) or base-catalyzed (Scheme 4.3-7) [44]. The acid-catalyzed reaction pathway involves the protonation of the respective



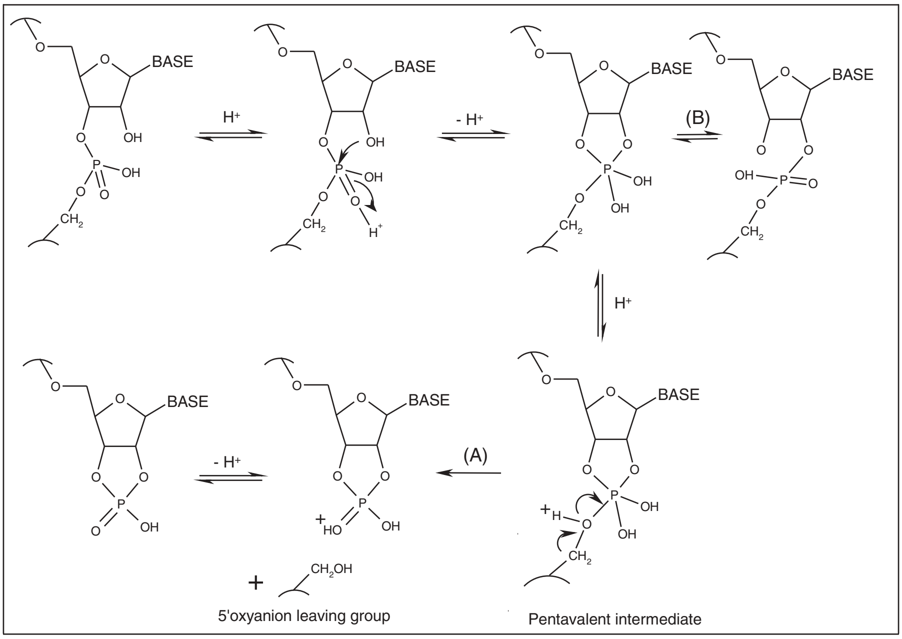
Scheme 4.3-6.



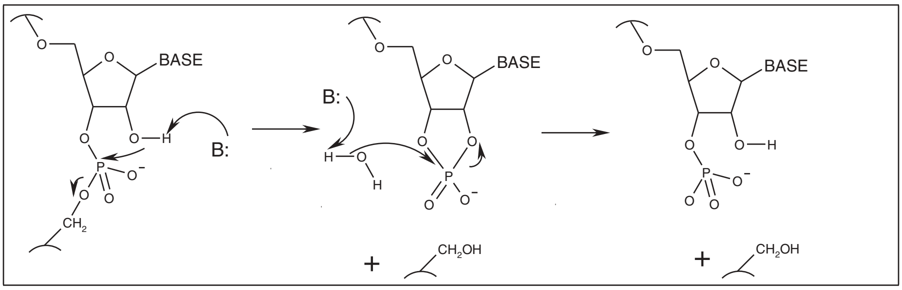
Scheme 4.3-7.

base, followed by a rate-limiting cleavage step to yield the C-1′ carbonium ion (oxocarbonium ion) (Scheme 4.3-6). Hence, the stability of the *N*-glycosidic bond can be enhanced or reduced by destabilizing or stabilizing the C-1′ carbonium ion being formed. The base-catalyzed hydrolytic reaction pathway (Scheme 4.3-7) proceeds by two S_N2 mechanisms at either C-8 or C-1′, which are dependent on temperature and the hydroxide ion concentration [44]. Depurination is more rapid with guanine and adenine, whereas the loss of cytosine and thymine (depyrimidation) proceeds at 5% of the depurination rate [45]. The double helical structure in DNA can offer only limited protection against depurination, as suggested by the mere 4-fold difference in depurination velocity observed between single-stranded and double-stranded DNAs. Introduction of a single break in the DNA backbone is capable of converting supercoiled plasmid DNA to the open circular form, and thus monitoring of this conversion affords a convenient and sensitive means of determining DNA stability [46]. For instance, V1JpHA plasmid DNA at 50°C and pH 7.4 underwent depurination and β-elimination with respective rate constants of $5.6 \times 10^{-11} s^{-1}$ and $1.4 \times 10^{-6} s^{-1}$, reflecting an accumulation of ~0.5 apurinic sites per plasmid after 2 years of storage at room temperature and a corresponding decrease of ~20% in supercoiled DNA content [43].

Hydrolysis of the Phosphoester Bond. The hydrophilic surface of multistranded oligonucleotides on the sugar-phosphate backbones is a prominent target for hydrolysis. The nucleophilic phosphodiester cleavage can be mediated through both intermolecular and intramolecular reactions. DNA, being devoid of the 2′-OH group, is much less susceptible to base-catalyzed hydrolysis than RNA [44]. As shown in Scheme 4.3-9, the intramolecular displacement of the 5′-linked nucleoside by the 2′-OH group results in the phosphodiester cleavage. In acid-catalyzed



Scheme 4.3-8.



Scheme 4.3-9.

hydrolysis, isomeri-zation may also be involved (Scheme 4.3-8) [44]. Generally, pyrimidine nucleoside 3′-phosphodiesters react faster than their purine counterparts.

The hydrolysis of phosphoester bond can be accelerated by several catalytic factors, including enhancement of the nucleophilicity of the 2′-oxygen (Scheme 4.3-9), stabilization of the leaving 5′ oxyanion group (Scheme 4.3-8), stabilization of the pentavalent intermediate (Scheme 4.3-8), and the presence of buffers (e.g., imidazole, morpholine, and carboxylates) and divalent or trivalent metal ions (e.g., Mg^{2+}, Zn^{2+}, Ca^{2+}, Cu^{2+}, and Fe^{3+}) [44].

Deamination of Pyrimidine and Purine Nucleosides. Deamination of pyrimidine nucleosides into uridines is a common hydrolytic degradation for nucleic acid-derived drugs under both acidic and basic conditions. The main targets of this

hydrolytic reaction are cytosine and its homologue 5-methylcytosine [45], whereas adenine and guanine are more prone to undergo deamination via the dediazoniation pathways [47]. In DNA, cytosine can be converted to uracil via direct deamination by base-catalyzed hydrolysis and parallel attack of a water molecule on the protonated base [44]. Consequently, the hydrolysis shows no strong pH dependence around pH 7.4. The reaction for single-stranded DNA is 150- to 200-fold more rapid than that for double-stranded DNA, reflecting the considerably better protection offered by the double helical structure [44, 47].

Purine nucleosides behave similarly to their pyrimidine counterparts, but their contribution to the overall degradation is insignificant [44]. For instance, adenine is converted to hypoxanthine in single-stranded DNA at only 2–3% of the rate of cytosine deamination [48].

4.3.1.3 Oxidation

Oxidation is one major chemical degradation pathway for biopharmaceuticals. The reaction involves reactive oxygen species such as hydroxyl radical (OH), hydrogen peroxide (H_2O_2), superoxide (O_2), and singlet oxygen ($^1O_2$), which can be generated by autooxidation, photoactivation, and metal catalyzed oxidation. Autooxidation refers to the oxidation in the sheer absence of oxidants. True autooxidation, being characterized by extremely slow reaction rate, is normally not regarded as an important degradation pathway for proteins [5, 49]. Oxidation can be catalyzed by various external factors, such as the presence of transition metal ions and ultraviolet (UV) irradiation [5, 49]. Among them, Fenton-type metal catalyzed oxidation is the most relevant generating source of reactive oxygen species in pharmaceutical formulations where contaminating peroxides may react with traces of redox-active transition metals such as iron or copper.

Metal Catalyzed Oxidation. Metal catalyzed oxidation is known to adversely influence the stability of proteins, peptides, plasmid DNAs, and nucleic acid-derived drugs by inducing conformational and functional changes in these biopharmaceuticals [43, 44, 49, 50]. In proteins and peptides where metal catalyzed oxidation is extremely common, the presence of trace metal ions can catalyze oxidation by either directly reacting with the side chains of certain amino acid residues to produce free radicals or complexing with oxygen to produce various reactive oxygen species. Due to site-specificity, a faster oxidation rate is commonly observed for amino acid residue having closer proximity to the metal-binding sites [51]. However, site-specific oxidation can be greatly reduced by replacement of the existing amino acid residues with their larger, bulkier, or charged counterparts, as in the case of condon-222 mutant subtilisin [52].

Generally, an electron donor or reducing agent known as prooxidant is also required to reduce the transition metal ions. The prooxidant may be present as contaminant in buffers or formulations. For instance, the presence of reducing sugar impurities in mannitol has been suggested as a possible cause for the oxidative degradation of L-367073, a potent fibrinogen receptor antagonist, which involves the formation of a Schiff base intermediate [53]. The role of prooxidants in the oxidative degradation of proteins and peptides has been experimentally verified

under controlled conditions. For instance, in the presence of oxygen, Fe^{3+} and an appropriate electron donor (e.g., ascorbic acid and dithiothreitol), the methionine residues in proteins are rapidly oxidized to methionine sulfoxides [49].

Although fewer stability studies have been reported for plasmid DNA and other nucleic acids than for proteins and peptides, the ability of trace metal ions to catalyze many oxidative processes (including Fenton reaction) even in the absence of hydrogen peroxide has been clearly demonstrated with the nucleic-acid-derived drugs [46]. Free radical oxidation is the major degradation process exhibited by plasmid DNA in pharmaceutical formulations in the absence of free radical scavengers and/or specific metal ion chelators [43]. Plasmid DNA formulations with demetalated phosphate buffers have significantly higher stability than those with non-demetalated buffers, strongly reflecting the important role of trace metal ions in the oxidative degradation of DNA [43].

Specific Oxidation Reactions in Proteins and Peptides. In general, the amino acid residues exposed on the surface of proteins are more susceptible to oxidation than those buried within the hydrophobic core. For instance, different methionine residues in proteins can exhibit substantial differences in oxidation rate, as observed for human growth hormone [54], granulocyte colony-stimulating factor [55], and human parathyroid hormone [56]. Such differences in methionine reactivity are consistent with the location and solvent accessibility of the methionine residues.

Oxidation in proteins and peptides are highly amino acid specific. The amino acid residues that are susceptible to oxidation generally fall into two groups, viz. those containing a sulphur atom (methionine, cysteine) and those with an aromatic side chain (histidine, tryptophan and tyrosine) [49].

Cysteine. The free thiol groups present in cysteine residue can undergo spontaneous oxidation to form either intra-/intermolecular disulfide bonds and cross-links or monomolecular by-products such as sulfenic acid, sulfinic acid and sulfonic acid [49]. The mechanisms of cysteine oxidation by hydrogen peroxide have been investigated in detail. In the absence of metal ions and at low concentration of H_2O_2, the oxidation of cysteine is a two-step nucleophilic reaction that generates cystine as the final product, the rate-determining step being the reaction of thiolate anion with the neutral H_2O_2 to form cysteine sulfenic acid as an intermediate [57]. At high concentration of H_2O_2, the percentage of disulfide formation declines due to cysteine depletion or operation of alternative reaction pathways for consumption of cysteine sulfenic acid, leading to increased formation of cysteine sulfonic acid [57].

The oxidation of cysteine to cystine disulfide is strongly catalyzed by transition metal ions. As the formation of disulfide bonds and cross-links can bring about not only changes in tertiary structure but also covalent dimerization and aggregation, oxidation of cysteine has been of particular concern with many biopharmaceuticals, including interleukin-1B and interleukin-2 [54]. The spatial orientation of thiol groups is an important factor affecting the oxidation of cysteine to cystine. As two cysteine residues are required for the reaction, the oxidation rate is usually inversely related to the distance between the thiol groups [49]. In 28 hen lysozyme variants with random coil structure, the extent of disulfide bond formation in each variant has been shown to be proportional to the distance between the cysteine residues [58]. As cysteine oxidation is favored by deprotonation of the thiol group, the local

structure governing the ionization or pK_a of cysteine residue will also influence the cysteine oxidation rate [49, 59]. As demonstrated using seminal ribonucleases segment 29–34 [60] and α-lactalbumin [61], introduction of an electronegative environment into the structures raises the pK_a of the thiol groups and reduces the cysteine oxidation rate. In contrast, cysteine[25] residue in papain, which displays a lower pK_a due to the presence of a nearby ionizable histidine group, is chemically more reactive than expected [59].

Methionine. The major oxidative degradation product of methionine is methionine sulfoxide. In acidic medium, methionine can be readily oxidized to methionine sulfoxide through a nucleophilic substitution reaction by alkyl hydrogen peroxides present in a solvent complex intermediate form [49]. In the presence of peracid, methionine can be oxidized to its sulfone derivative [54].

Light exposure, storage temperature, and oxygen level can all significantly influence the oxidation rates of protein pharmaceuticals [62, 63]. Local structure in the immediate vicinity of an amino acid residue in peptides may also affect the oxidation pattern of the residue. For instance, oxidation of threonine-methionine promotes the cleavage of the side chain of threonine residue [64]. Histidine facilitates the oxidation of neighboring methionine, and *C*-terminal methionine is oxidized more readily than the *N*-terminal or intra-chain methionine [54]. In addition, the formation of methionine sulfoxide is pH dependent, being favored at low pHs [54] and different methionine residues in the same protein molecule exhibit different oxidation rates, which also vary with pH [55, 56]. In human parathyroid hormone, the oxidation of the two methionine residues is virtually independent of pH between 4 and 8, but the rate of oxidation increases at pH 2 [56]. In contrast, the four methionine residues in granulocyte colony-stimulating factor show much larger differences in oxidation rate with H_2O_2 at various pHs [55]. Such pH dependence of the methonine oxidation has been attributed to the changes in local environment of the methonine residues in response to pH changes, i.e., the protonation or deprotonation of the nitrogen atoms in the neighboring histidine groups.

Aromatic Amino Acids (Histidine, Tryptophan and Tyrosine). Histidine residues are highly susceptible to oxidation, as shown for human growth hormone [65] and relaxin [66]. The resulting degradation products are aspartic acid, asparagines, and 2-oxo-histidine [65, 67]. Metal catalyzed oxidation of histidine may alter the secondary/tertiary structures of proteins. As has been demonstrated, oxidation of the human relaxin histidine[A(12)], which exists in an extended loop that joins two α-helices, alters the protein conformation, resulting in pH-dependent protein aggregation and precipitation [66, 68].

Tryptophan is also sensitive to oxidation, yielding mostly N′-formylkynurenine and 3-hydroxykynurenine [69]. The formation of N′-formylkynurenine can be activated by photoionization of tryptophan residues arising from the formation of solvated electrons [70]. The reaction is also catalyzed by the presence of metal ions [69]. Tryptophan residue can also mediate photooxidation of the disulfide bond in bovine somatotropin without being oxidized itself [70].

Tyrosine is also prone to oxidation, yielding 3,4-dihydrophenylalanine and dityrosine cross-link as the major reaction products [69]. For example, dityrosine-linked dimer was formed upon photoactivation of γB-crystallin at 445 nm [71].

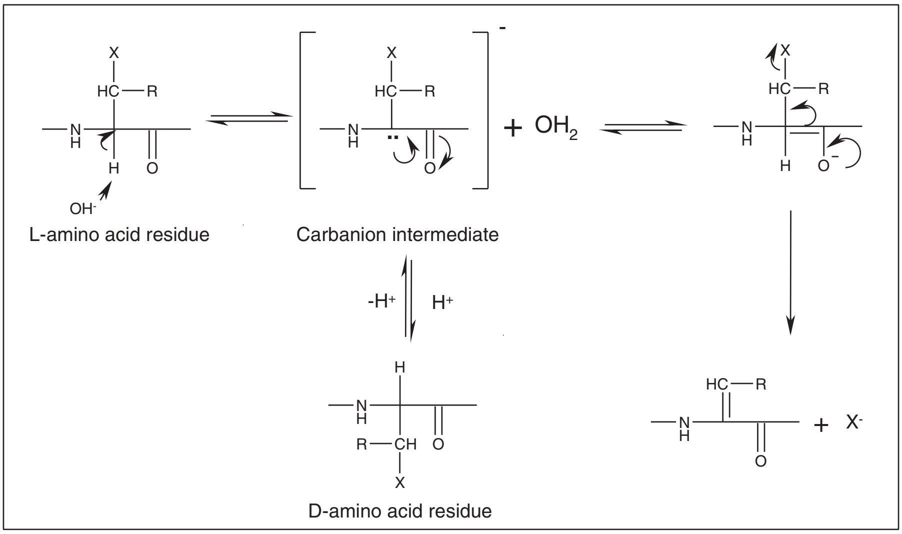
Other Amino Acid Residues. N-terminal glycine residue is also a potential site for oxidation. Oxidation of Pexiganan has been reported to generate N-glyoxylyl-des-gly$_1$-pexiganan, which can be further decomposed to yield other products, as verified by high-performance liquid chromatography (HPLC) and mass spectrometry [72].

Specific Oxidation Reactions in Nucleic Acids. Nucleobases and sugar moieties are the oxidation sites of nucleic acids. Similar to metal catalyzed oxidation in proteins and peptides, DNA damage through oxidative stress can also be induced by Fenton-type reactions involving transition metal ions, e.g., Fe^{2+} and Cu^{2+} [73]. The electron-rich purines and pyrimidines are the prime targets for the reaction with electrophilic oxidizing and photooxidizing agents [74, 75], and hydrogen abstraction and radical addition are the two known mechanisms responsible for the oxidation of aromatic nucleobases [44]. Such oxidation reactions will result in base cleavage and subsequent strand scission [76, 78]. As nucleobase oxidation removes electron density from the heterocycle, the oxidized nucleobase is a better leaving group, leading to an enhancement of hydrolytic depurination and depyrimidation [78]. Guanine, being the most readily oxidized site among the nucleobases, can be activated by light and catalyzed by trace metal ions to yield a wide range of oxidation products such as 8-hydroxyguanine, xanthine [76], 8-oxoguanine (8-oxoG), and 2,6-diamino-4-hydroxy-5-formamidopyrimidine [78]. Of all oxidation products of guanine, 8-oxoG is the most common oxidative lesion observed in duplex DNA, and is generally regarded as a key lesion in toxicological assessment [78]. Another well-characterized guanine lesion is 7,8-dihydro-8-oxo2′-deoxyguanosine (8-OH-dG) [79], which has been used as a degradation marker for a plasmid DNA in pharmaceutical formulation [43]. Adenine can also be oxidized readily, although significantly fewer oxidative lesions are formed because of its higher one-electron redox potential [78].

For the sugar moieties, the only oxidation mechanism is radical-mediated hydrogen abstraction, which can be induced by Fenton- or radiation-generated hydroxyl radicals [80]. Various hydrogen atoms in sugar moieties, such as H-1′, H-2′, H-3′, H-4′, and H-5′, are all potential sites for abstraction, although not all hydrogen atoms of deoxyribose in B-DNA have equal probability of being abstracted from duplex DNA [80]. The reaction depends on the helical structure of the nucleic acid, the orientation of the oxidant relative to the sugar as well as the stability of the carbon-centered radical being formed [44, 80]. As resonance stabilization is more difficult with sugar moieties than with nucleobases, the sugar moieties are less-favorable targets than nucleobases for radical attacks. The accessibility of the C–H bond also affects the rate and selectivity of hydrogen abstraction. For instance, oxidation of sugar moieties in the B-form of DNA mainly occurs at C-4′ due to its accessibility [73, 78, 80].

4.3.1.4 β-Elimination in Nucleic Acids, Proteins and Peptides

The two-step process of depurination (see the "Depurination and depyrimidation" Subsection in Section 4.3.1.2) and β-elimination is an important DNA degradation pathway in aqueous medium [45]. Upon depurination, the apurinic site contains a chemically altered sugar that alternates between a cyclic furanose form and an



Scheme 4.3-10.

acyclic form containing an aldehyde functional group on the 1′ carbon. The aldehyde form of the sugar then undergoes β-elimination, which commences with the abstraction of a proton from the 2′ carbon by the OH^-, leading to strand breakage on the 3′ carbon of the abasic site [81].

In proteins and peptides, the β-elimination step involves the abstraction of a proton from the α-carbon of an amino acid residue in the peptide chain to form a carbanion intermediate (Scheme 4.3-10) [3]. Racemization can then occur via the addition of a proton to the opposite plane of the intermediate. Alternatively, the carbanion intermediate undergoes further reaction to form a dehydroalanine residue (Scheme 4.3-10) [3]. Cysteine, serine, threonine, phenylalanine, and lysine are the amino acid residues known to undergo β-elimination in peptides and proteins. Protein pharmaceuticals that can decompose by this reaction route include leuprolide [82, 83], salmon calcitonin [34], and insulin [84]. Leuprolide, which is formulated as a highly concentrated solution in DMSO for delivery in DUROS osmotic implant, shows increased β-elimination for the serine[4] residue in nonaqueous media [82, 83]. For insulin, the covalent and noncovalent aggregation of lyophilized preparation has been attributed to the intermolecular thiol-catalyzed disulfide interchange following β-elimination of an intact disulfide bridge in the insulin molecule [84]. This degradation process can be accelerated by elevated temperature; increased moisture content of the insulin, lyophilization, and/or dissolution of the insulin in alkaline media; as well as the presence of Cu^{2+} (catalyst for the oxidation of free thiols).

4.3.1.5 Maillard Reaction in Nucleic Acids, Proteins, and Peptides

Maillard reaction, which is responsible for the nonenzymatic browning of materials, has been extensively investigated with food materials, but less so with pharmaceutical substances. The reaction consists of an initial reaction of reducing sugars with

amino or free amine groups in proteins, peptides, or nucleic acids, followed by Schiff base conversion and the formation of brown pigments via Amadori and Heyns rearrangement [85, 86]. For proteins and peptides, the amino acid residue involved in the reaction is usually lysine because of its free ε-amino group, but other bases such as arginine, asparagine, and glutamine can also react with the sugars [86]. In nucleic acids, the reaction may occur between the aldehyde of the sugar at the apurinic sites and the amino groups on the DNA bases in another plasmid molecule to produce concatamers [46]. Biopharmaceuticals documented to undergo Maillard reaction include glucagon [85], human relaxin [87], β-lactoglobulin variant A [88], lysozyme [89, 90], recombinant human serum albumin [90], calf thymus DNA [91], and plasmid pBR322 DNA [92].

Maillard reaction can give rise to significant changes/losses in physico-chemical properties and pharmacological activities of therapeutic proteins. Of particular concern in this regard is the modification of protein antigenicity, which is associated with the formation of advanced glycation endproduct (AGE) [93]. Glucose, a monosaccharide with reducing property, is particularly reactive toward the amino acid residues in proteins and peptides [87–90], whereas other sugars such as trehalose and mannitol have very little effect, as attested by the findings of the formulation studies with these sugars on glucagons [85] and relaxin [87]. Sucrose can also cause glycation when it is hydrolyzed to glucose and fructose by heat treatment, as observed for β-lactoglobulin variant A, lysozyme, and rHSA during antiviral heat bioprocessing [88–90].

As with proteins and peptides, nucleic acids can suffer substantial losses of biological activities as a result of Maillard reaction upon aging [91, 92]. Age-related dysfunction in gene expression has been demonstrated in DNA modified by reducing agents [91]. In addition, the amino groups of DNA have been shown to react nonenzymatically with reducing sugars (i.e., glucose) to afford a yellow-brown coloration, and the adducts formed *in vitro* have been found to decrease the transfection ability of f1 phage DNA [91, 92].

4.3.1.6 Covalent Dimerization and Polymerization in Proteins

Precipitation is a macroscopic process characterized by a visible change of an otherwise clear solution in the form of an increase in solution viscosity, clouding of solution, or phase separation of solid materials. The formation of precipitates may be due to covalent polymerization and/or noncovalent aggregation (Section 4.3.2.2). In covalent polymerization, dimer formation usually precedes the precipitation, and the phenomenon is best illustrated by insulin, which has been extensively reported to form covalent dimers.

Covalent dimer is the main degradation product of insulin upon storage [94]. Covalent trimer, tetramer, oligo-, and polymer formation is also possible with insulin when stored at ambient or higher temperatures. In general, the rate of insulin polymerization is virtually independent of the protein source (e.g., bovine, porcine, and human), but it varies with the composition and formulation of the protein and, for the isophane preparation, with the strength of preparation [94]. The rate of polymerization is one order of magnitude slower than insulin hydrolysis except for the NPH preparations [94, 95]. The covalent aggregation of insulin can be inhibited by self-association at high insulin concentration [9]. Both deamidation

and covalent dimer formation in human insulin solution at low pH seem to originate from a common cyclic anhydride intermediate [96]. Covalent dimer formation of human insulin is also evident in lyophilized solid state, accounting for no more than 15% of the total degradation [97]. Similar to the effect observed in solution, an increase in pH favors dimerization in lyophilized insulin, which can be ascribed to the increased nucleophilicity of the terminal amino groups after deprotonation. However, covalent dimerization can be almost completely suppressed by incorporating trehalose into the lyophilized matrix, which restricts the molecular mobility of insulin and keeps the protein molecules in a fully dispersed state.

Besides insulin, other biopharmaceuticals known to exhibit covalent polymerization include recombinant tumor necrosis factor-alpha, which forms nonreducible dimers and oligomers [98], and human insulin-like growth factor I, which is prone to covalent aggregation [99].

4.3.2 PHYSICAL INSTABILITY

4.3.2.1 Denaturation

Denaturation refers to an alteration of the global fold of a biopharmaceutical with higher order structures without an accompanying change in the primary structure. For proteins, these higher order structures refer to the secondary, tertiary, and quaternary structures with different levels of complexity. Although nucleic acids are structurally less complex than proteins, more elaborate structures such as double helix and supercoiling exist in DNAs, and many RNAs also have well-defined tertiary structures. Any conformational changes in these structures can lead to denaturation of these biopharmaceuticals.

The conformational integrity of native protein is maintained by a proper balance of weak nonbonding forces. Conceptually, an equilibrium exists between the native-folded and the denatured-unfolded forms of the protein, with or without the involvement of unfolding intermediate(s), or molten globule(s), in definable thermodynamic state(s). As the free energy of protein unfolding ΔG_{unf}, is typically in the range of 10–20 kcal/mol, the native structure of the protein is readily disrupted by a change of environment (e.g., application of heat, change of pH, and addition of detergents or chaotropes) [100]. Such structural perturbation, which is either permanent or temporary, leads to a change of conformationally sensitive physical properties (e.g., optical rotation, viscosity, and UV absorption) and, most seriously, to a concomitant loss of biological activities. If the denaturation process is reversible, the loss of native structure can be recovered once the stress is removed. However, no such structure recovery is possible with irreversible denaturation involving covalent bond formation such as disulfide exchange or cross-linking. Irreversible denaturation also leads to aggregation and precipitation with accompanying changes in the secondary and/or tertiary structures of the proteins. The soluble aggregates derived from denatured-unfolded protein and unfolding protein intermediates are prone to aggregation and precipitation in pharmaceutical formulation, resulting in a severe activity loss, as illustrated by recombinant human granulocyte colony stimulating factor [101]. Addition of sucrose to this protein brings about an increase in ΔG_{unf} and a consequential decrease in aggregation and an increase in conformational stability.

Almost all water-soluble proteins are denatured by heat treatment. Although some denaturation processes follow the Arrhenius kinetics, the ΔG_{unf} in most cases follow a parabolic dependence on temperature, as depicted by the following equation [100]:

$$\Delta G_{\text{unf}} = \Delta H_m (1 - T/T_m) - \Delta C_p (T_m - T) + T \ln(T/T_m) \qquad (4.3\text{-}1)$$

where ΔH_m is enthalpy of melting, ΔC_p is the specific heat capacity, and T_m is the melting temperature. In an actual situation, once the temperature is raised and a significant fraction of the protein ensemble is unfolded, aggregation and/or precipitation can proceed rapidly, resulting in irreversible denaturation. In addition to heat denaturation, cold denaturation of proteins can occur during freeze-drying. In general, freeze-drying causes considerable conformational changes and aggregation in protein molecules, thereby promoting the formation of the β-sheet structure at the expense of the α-helix and random structures [102].

Protein stability is highly sensitive to pH changes and decreases sharply at acidic or basic pH. Because of the differences in pK_a of certain amino acid groups between the native and unfolded proteins, protons released in response to pH changes can play an important role in the unfolding process [100]. It has been shown that protein conformational fluctuations generally agree with the predictions based on the pK_a values of the titrating groups in the protein [103]. Aside from pH manipulation, protein unfolding can be achieved with chaotropic agents (e.g., urea and guanidine hydrochloride). However, in contrast to the less-than-complete protein unfolding induced by thermal denaturation, the denatured state produced by such chaotropes is virtually devoid of structure, resembling a random coil conformation [104].

Subjection of duplex DNA to various stress factors such as heat, pH, and ionic strength can lead to a collapse of the native DNA structure. The two complementary strands separate and assume a random coil conformation with concomitant changes in physical properties (e.g., viscosity and UV absorbance) and biological activities. The thermodynamic stability of a nucleic acid duplex is a complex function of temperature and pressure, being strongly dependent on the denaturation temperature T_m [105, 106]. Interestingly, the relationship between the free energy associated with helix-to-coil transitions of nucleic acid duplexes ΔG_m and the corresponding ΔH_m, T_m, and ΔC_p conforms to that predicted by Equation (4.3-1) for the protein unfolding process, where a parabolic curve is expected [106]. Cold denaturation of nucleic acid duplex can also occur when the temperature is held below −120°C at atmospheric pressure [105].

Duplex stability is dependent on DNA conformation. Classic B conformation has a lower free energy of helix-to-coil transition and lower T_m than B′ conformation, whereas B′ conformation has a higher thermal stability than A conformation [106]. Base pairs also influence duplex stability.

4.3.2.2 Aggregation and Precipitation

Aggregation and precipitation are common problems of instability with protein biopharmaceuticals, e.g., keratinocyte growth factor [107], human immunoglobulin [108], and human serum albumin [109]. In clinical practice, an aggregation level of

as low as 1% over a period of 2 years is deemed unacceptable [110]. Aggregation differs from self-association in that it is confined only to non-native proteins, and it enamates from a conformational intermediate produced during folding or denaturation of the proteins, whereas self-association occurs in native proteins in response to deliberate changes of solvent environment (e.g., pH, ionic strength, and solvent composition) to effect crystallization or isoelectric precipitation.

Protein aggregation can be described as a two-step process. The first step entails protein unfolding and exposure of buried hydrophobic residues to the aqueous solvent. The second step involves intermolecular interactions among the exposed hydrophobic residues of the unfolded protein intermediates, which are thermodynamically favored by the tendency of the exposed hydrophobic amino acid residues to minimize their contact with the aqueous medium. The reaction is site specific, as the initial stage of aggregation involves the interaction of one protein molecule with another at specific sites. Two such sites per protein molecule are sufficient for aggregation to proceed longitudinally, leading to the formation of long fibers. As more of these stable aggregates comprising a few molecules are formed (nucleation), they will develop into larger aggregates (growth) and eventually into floccules, which will precipitate from the solution once their solubility limit is exceeded.

In aqueous solution, non-native protein aggregation is dependent on various factors, such as temperature, solution pH, salt type, and concentration as well as the presence of ligands, cosolutes, preservatives, and surfactants [111]. Intrinsic conformational stability of native proteins as well as the colloidal stability between protein molecules may play a crucial role in the aggregation process. As aggregation requires the presence of two or more protein molecules, the aggregation reaction rate is expected to be higher because of increased probability of molecular collision [112]. However, the problem of protein aggregation in solution cannot be solved simply by preparing the protein in solid form alone, as solid phase aggregation is also common with lyophilized or freeze-dried formulations. There are a wide variety of mechanisms responsible for moisture-mediated solid-phase aggregation, encompassing thiol-disulfide interchange, thiol-catalyzed disulfide exchange after β-elimination, non-covalent aggregation, and non-disulfide covalent aggregation [113].

Aggregation can lower protein potency simply by decreasing the effective protein concentration. Moreover, it can increase the immunogenicity of proteins, as observed for insulin, human growth hormone, and recombinant human interferon-α2a [114]. Various low-molecular-weight excipients have been investigated for their potential to minimize protein aggregation or stabilize protein conformation [112]. Simple sugars, polyhydric alcohols, and amino acids have all been shown to effectively prevent freeze/thaw-induced aggregation in chimeric L6, a mouse-human monoclonal antibody [115]. Sucrose is known to inhibit the aggregation of recombinant human granulocyte colony stimulating factor [116]. Sorbitol has also been demonstrated to reduce moisture-induced aggregation in tetanus and diphtheria toxoids [117]. β-Cyclodextrins have also been found to inhibit the aggregation of recombinant human growth hormone [118]. However, there are also excipients that can adversely impact the protein aggregation and precipitation. For example, benzyl alcohol can induce precipitation of human insulin-like growth factor I from solution [119] as well as aggregation of human interleukin-1 receptor antagonist (a predominantly β-sheet protein) in aqueous solution [120] and reconstituted lyophilized formulation [121].

4.3.2.3 Adsorption

Interfaces between two separate phases, such as air/water, oil/water, and solid/water, are potential adsorption sites of biopharmaceuticals. Adsorption often involves simple diffusion of surface-active solute molecules in the bulk to the interface, and hence the rate of adsorption is generally dependent on the solute concentration. At saturation, a close packed monolayer of protein molecules corresponding to 0.1 to 0.5 μg/cm^2 is normally formed at the interface [122], and this adsorption behavior is of particular concern for high-potency therapeutic proteins. However, certain proteins do not conform to such saturation-limited adsorption behavior and tend to show increased adsorption with increasing protein concentration, attaining a local protein concentration at the interface 1000 times higher than the initial concentration in the bulk solution [123].

The surface activity resulting from different amino acid compositions of polypeptides has an important bearing on the extent of surface adsorption. As amino acids can be hydrophobic (e.g., tryptophan, phenylalanine, and isoleucine), hydrophilic (e.g., serine and threonine), negatively charged (e.g., aspartic acid and glutamic acid), or positively charged (e.g., histidine), the proteins involved can potentially adsorb on to solids such as plastics and glasses with different affinities. Owing to their intrinsic polyelectrolyte nature, the adsorption of proteins on solids is highly pH dependent, reaching a maximum at their respective isoelectric points (p*I*s) [122]. It has been demonstrated that recombinant human interleukin 11, which is monomeric and highly basic (pI > 10.5), displays a nonspecific loss to container in alkaline solution [32]. Surface adsorption alone can cause more than 40% activity reduction of interleukin 11 in solution after 3 hours of storage at room temperature [124].

Upon adsorption to container, conformational changes can occur in the higher order structures of proteins. As hydrophobic amino acid residues tend to stay inside a protein (i.e., away from the aqueous environment), surface interaction may unfold the protein to expose the inside structure, thereby leading to structural rearrangement of the protein. For instance, it has been shown that the native structure of α-helices and extended loop bands of recombinant interleukin 2 disappeared, whereas the β-sheet appeared upon contact with a pump-based delivery system (borosilicate glass pump reservoir and catheter tubing), resulting in irreversible structural changes and major biological activity loss of the protein [125].

Apart from solid surfaces, liquid surfaces are potential sites for protein adsorption. By creating a large surface area, agitation may induce protein adsorption at the liquid surface where the area occupied per unit mass of protein in the monolayer region is high (~1 m^2/mg) compared with that at the solid–liquid interface (~0.1 m^2/mg) [122]. The adsorption process coupled with interfacial and shear forces may lead to protein denaturation through unfolding as well as aggregation and precipitation (Section 4.3.2.2), as observed for recombinant factor VIII SQ [126].

Addition of surface-active agents (e.g., polysorbates) can prevent protein adsorption and stabilize the protein preparation. Numerous reports have documented the stabilizing effect of surface-active agents against adsorption of biotechnological products. For example, polysorbate-80 exerts a primary stabilizing effect on adenovirus type-5 based vaccine by inhibiting adsorption of the vaccine to glass vials

[127]. The presence of 0.12% polysorbate-20 reduces the adsorption of recombinant human interferon-γ to both air–liquid and ice–liquid interfaces [128]. Similarly, the presence of polysorbate-80 or polysorbate-20 reduces surface adsorption of recombinant factor VIII SQ and, hence, the agitation-induced denaturation of the protein [126]. Inclusion of albumin, which minimizes the contact of proteins with glass surface, may also help to stabilize the proteins against glass adsorption, as demonstrated for salmon calcitonin [129].

Paradoxically, the adsorption process can be used to stabilize biopharmaceuticals, particularly vaccines [130]. Aluminum salts have been widely used as adjuvants in intramuscular vaccine injections. Novel vaccine formulations containing aluminum are available; for example, alum-adsorbed hepatitis B surface antigen and diphtheria-tetanus toxoid vaccines have been optimized for epidermal immunization in powder form [131].

4.3.3 CONSIDERATIONS IN THE STABILITY TESTING OF BIOPHARMACEUTICALS

4.3.3.1 Temperature

The stability of pharmaceuticals, including biopharmaceuticals, is highly temperature dependent. For most small organic molecules, thermal degradation generally follows Arrhenius kinetics. However, many biomaterials, e.g., proteins, do not exhibit Arrhenius degradation kinetics even over a narrow temperature range, which can be attributed to phase transitions, pH shifts, poor relative humidity control at elevated or subambient temperature, and involvement of complex reaction mechanisms [132]. Multistep reaction pathways are particularly common in biopharmaceuticals because of the existence of higher order structures. For instance, with recombinant bovine granulocyte colony stimulating factor, a reversible equilibrium between the native protein and an intermediate state is established, followed by irreversible aggregation [133]. Although individual denaturation steps seem to obey the Arrhenius law, the overall kinetic behavior for product formation may not [132, 133]. Thus, for protein pharmaceuticals, extrapolated shelf-life prediction from accelerated stability test must be viewed with caution and real-time stability monitoring should also be conducted whenever feasible.

As many therapeutic proteins are formulated in aqueous solution and stored at 2–8°C, they are liable to cold denaturation at such low temperatures and possibly to freezing/thawing inactivation arising from temperature fluctuation during storage or handling. When a protein solution freezes, water crystallizes out as solid ice and the solution becomes more concentrated in the protein and salt components present, causing dramatic changes in pH and ionic strength and hence protein inactivation [134]. For instance, during freezing of sodium phosphate solutions, crystallization of the disodium salt can reduce the pH by as much as 3 units [135]. The effects of freezing and thawing rates on the stability of model proteins have been investigated in the absence of cryoprotectants, and higher activity recovery at a slower freezing rate and a faster thawing rate has been observed [136]. During fast freezing, small ice crystals are preferentially formed and the associated increase in total surface area of the ice–liquid interface will enhance the exposure of protein molecules to

the interface and increase the protein damage. Upon thawing, additional damage to proteins may be caused by recrystallization [136]. Many biopharmaceuticals, including recombinant human interferon-γ [135], tetanus toxoid conjugate vaccines [137], and pCMVβ-gal plamid DNA/lipid complexes [138] show a reduction in activity upon freezing/thawing. To circumvent the aforementioned protein inactivation problems, various excipients have been used in biopharmaceutical formulations. For example, Tween 80, a polysorbate surfactant, has proved useful for reducing surface-induced protein denaturation during freezing [139], and glycine can also stabilize proteins through the preferential exclusion mechanism [135].

4.3.3.2 Moisture

Moisture is well documented to adversely affect the chemical stability of solid biopharmaceuticals. The presence of water enhances the mobility and flexibility of the bioactive macromolecules in solid excipient matrix, thereby facilitating their rearrangement and increasing their susceptibility to chemical degradation. For instance, the deamidation rate of an asparagine containing hexapeptide in lyophilized poly(vinyl alcohol) (PVA) and poly(vinyl pyrrolidone) (PVP) increases with increasing moisture uptake and water activity of the system [140]. The asparagine deamidation seems to correlate closely with the extent of water-induced plasticization of PVA and PVP matrices (as determined by the respective glass transition temperature T_g), suggesting that the chemical stability of the peptide may be predicted by the physical state of the formulation [140]. Similarly, aspartate isomerization in humanized monoclonal antibody, which can be accelerated at elevated temperatures, has been observed to follow the Arrhenius law above the T_g of a lyophilized formulation [141].

The presence of moisture can also reduce physical stability. The mechanisms of moisture-induced aggregation are well documented and have been exemplified by a good number of solid biopharmaceuticals, including salmon calcitonin spray-dried powders for inhalation [142], human serum albumin [143], and recombinant human albumin [109]. To prevent such protein aggregation, excipients are often employed in protein formulation. The excipients, which comprise mostly sugars such as mannitol, lactose, trehalose, and cellobiose, prevent protein aggregation by occupying the water-binding sites of protein in the dried state [144]. However, these sugar excipients may also present formulation problems, notably sugar crystallization at high excipient-to-protein ratios [144] and phase separation due to prevalent sugar–sugar interactions [145].

The conventional wisdom of moisture content control for biopharmaceuticals is "the drier, the better." As has been demonstrated with a lyophilized humanized monoclonal antibody formulation, moist cakes tend to have higher aggregation rates than drier samples if stored above their T_g [141]. However, excessive moisture removal can destabilize the protein, as observed with bovine immunoglobulin [146].

4.3.3.3 Light and Ionizing Radiation

Eletromagnetic radiations of different wavelengths, i.e., UV-visible light and x-ray, are known to induce degradation in proteins [147]. Radiation, which is commonly employed for sterilization purpose, can generate free radicals and lead to peptide

chain cleavage and aggregation in solid protein pharmaceuticals [147]. In aqueous solution, the protein may also degrade through the destruction of the amino acid residues by the hydroxyl radicals and electrons produced from water molecules [147].

As biopharmaceuticals are formulated mostly for parenteral administration, complete shielding of light is impossible. Although amber glass containers can be used for shielding against UV light, their utility in light protection is often limited by the glass thickness. Light-induced degradation or photodegradation can be minimized by formulation into solid dosage forms. By formulating into a lyophilized form, recombinant human factor VIII showed no significant loss of activity after accelerated photostability testing, whereas the reconstituted preparation displayed partial activity loss after similar light exposure, and the observed photodegradation could be effectively prevented by packaging the protein in tinfoil wrap [148].

Nucleic acids are also susceptible to UV light. DNA molecules absorb photon energy at wavelengths below 320 nm, which gives rise to the widely reported mutagenic DNA damage. DNA photocleavage can occur at both deoxyriboses and nucleobases [75]. The presence of photosensitizers, such as psoralen, chlorpromazine, and fluoroquinolones, may promote the light-induced degradation by generating reactive oxygen radicals or singlet oxygens, which then interact with DNA to produce damage [149].

4.3.3.4 Physical Stress

Biopharmaceuticals may be inactivated by physical stress associated with vial filling, shipping, storage, and handling. Insulin is a well-known example of agitation-induced instability, and patients are advised to avoid vigorous shaking of the insulin preparation. Shaking is known to accelerate the degradation of insulin by way of covalent dimerization [150]. To assess the adverse impact of agitation on the stability of insulin preparations, two automated physical stress tests, viz., the Temperature Cycling and Resuspension Test (TCRT) and the High Temperature and Extreme Agitation Test (HTEAT), have been applied to a commercial portable insulin pen-cartridge device [151]. TCRT involves temperature cycling (25–37°C) in an incubator unit combined with resuspension (three sets of 10 rolls plus 10 inversions) conducted twice daily, whereas HTEAT requires continuous high-temperature (37°C) exposure in an incubator unit combined with periodic daily agitation for 4 hours at 30 rpm. These two tests afford a rapid means for screening potential aggregation during the formulation development of proteins [151].

Apart from insulin, monomeric recombinant human growth hormone has been shown to aggregate rapidly within 10 hours of shaking [152]. The presence of Tween 20, a nonionic surfactant, at an excipient : protein molar ratio larger than 4 effectively inhibited this aggregation. Similar aggregation was observed with IgG1-antibody upon the application of physical stress. However, differences in aggregation mechanism exist among different mechanical stress methods (e.g., shaking and stirring) [153]. Moreover, the aggregation kinetics is dependent on the shear rate applied, and trimer formation is particularly evident at a high shear rate, as observed for human serum albumin [154]. Even simple vortexing for just 1 minute can cause substantial aggregation and precipitation, as shown for recombinant human growth hormone [155].

Agitation-induced instability is not limited to protein pharmaceuticals. For instance, agitation has been shown to significantly reduce transfection rates in pCMVβ-gal, a plasmid DNA, and in complexes prepared with three different commercially available lipid formulations, namely, DMRIE-C, lipofectAMINE, and DOTAP:DOPE [138].

4.3.3.5 Freeze-Drying and Spray-Drying

Lyophilization, the most widely used process for preparing solid proteins, consists of two major steps: freezing of a protein solution and drying of the frozen solid under vacuum. The drying step can be further divided into two phases, namely, primary drying (removal of frozen water) and secondary drying (removal of the non-frozen bound water) [156]. As alluded to, freezing can cause cold denaturation and introduce additional stresses to the proteins through ice crystallization (Section 4.3.3.1). Likewise, drying can bring about protein degradation. By removing the hydration shell covering the protein surface, the native state of protein may be disrupted, resulting in denaturation [157]. Water molecules may also be an integral part of protein active sites. Removal of these functional water molecules can inactivate proteins during dehydration [157]. Thus, it is perhaps not surprising that freeze-drying-induced degradation is common with protein pharmaceuticals, e.g., *Humicola lanuginose* lipase [158], lysozyme [159], and recombinant human factor XIII [160], as well as nucleic-acid-derived drugs, e.g., poly((2-dimethylamino)ethyl methacrylate)-based pCMV-lacZ plasmid gene delivery system [161] and cationic lipid-protamine-DNA complexes [162]. Aggregate formation is also apparent during storage of freeze-dried biotechnological products, e.g., ribonuclease A [163], and sugars, polyols, and polymers are the excipients commonly used for stabilizing them [157].

Spray-drying, a single step operation that converts a liquid feed to a dried particulate form, has proved useful for producing powders within the respirable range for pulmonary delivery of biopharmaceuticals. Many of these products, including recombinant human growth hormone [164], recombinant human deoxyribonucleases [165], and recombinant humanized anti-immunoglobulin E monoclonal antibody (rhuMAbE25), have been prepared by the spray-drying process [166]. As spray-drying of these proteins alone in solutions can result in unfolding, aggregation, and inactivation because of temperature and interfacial effects, stabilizers such as polysorbates [164, 167], mannitol [166], sucrose, and trehalose [168], are usually added to improve the processing and storage stability of these preparations [169].

4.3.3.6 Excipients

The inclusion of chemical excipients/additives can inhibit or slow degradation reaction in biotechnological products. In the case of metal catalyzed oxidation, chelating agents such as ethylene diamine tetra acetic acid (EDTA) can suppress the reaction by removing trace transition metals ions from the bulk solution. Some sugars and polyols (mannitol, glucose, glycerol, ethylene glycol) can inhibit metal catalyzed oxidation by complexation with the transition metal ions, whereas polymeric additives such as dextran may function as a hydroxyl radical scavenger [170]. Sodium thiosulfate has been reported to reduce the formation of a disulfide-linked high-molecular-weight species of OKT3 antibody in solution [171]. However,

precautions must be taken when using these excipients for stabilization purposes. As has been reported, inclusion of aliphatic alcohols as inhibitors of metal catalyzed oxidation can give rise to cosolvent-induced perturbation of the metal binding site in recombinant human growth hormone [172].

Although several excipients have been made available for prolonging the shelf-life of biopharmaceuticals, potential reactions between excipients and actives may adversely influence the overall stability of the formulations. For instance, excipients containing carbonyl functional groups, such as PVP, can form a covalent adduct with peptides and proteins containing primary amines (i.e., N-terminus and lysine side chain) at high temperatures (70°C) and low RH (~0%) [173]. The presence of sucrose can promote methionine oxidation in recombinant factor VIIa, possibly due to the increase of chemical potential or a small conformational change in microenvironment [174]. Furthermore, excipients may be contaminated with traces of impurities, such as transition metals and reducing agents, which can compromise the stability of the protein products. For instance, both food-grade and pharmaceutical-grade polysorbates often contain traces of alkylhydroperoxide and hydrogen peroxide arising from the bleaching step in the synthetic process [175]. During storage, polysorbates may also decompose to peroxides, and the decomposition is accelerated by increased exposure to air and light, elevated temperature, and the trace presence of metal catalysts [54, 175].

4.3.4 REGULATORY REQUIREMENTS IN THE STABILITY TESTING OF BIOPHARMACEUTICALS

In the development of stability testing protocols for biotechnological/biological products, all relevant regulatory guidelines must be closely followed. The International Conference on Harmonization (ICH) guidelines for stability testing are widely adopted and are available online (http://www.ich.org). It is important to check the logistics and requirements of the appropriate stability programs before initiation of the stability testing. These guidelines have defined the storage conditions for long-term, intermediate, and accelerated stability testing for different climatic zones [Q1A(R2); Q1C; Q1F]. Photostability is also considered under the relevant section [Q1B]. Experimental design and data analysis with specific requirements also constitute an important part of the stability testing programs [Q1D; Q1E]. Given the complexity of biotechnological products and their sensitivity to environmental factors, such as temperature, humidity, light, oxygen, ionic strength, and shear stress, additional guidelines are available for assuring their quality and Q5B aims to regulate the stability testing of these products. Apart from the method of batch selection for the testing, Q5B guidelines have a particular emphasis on the establishment of stability-indicating profiles for the active drug substances. Potency testing should be included in the stability assessment, and the purity of biotechnological products should normally be determined by more than one method.

4.3.5 FORMULATION AND CHARACTERIZATION OF BIOPHARMACEUTICALS

As discussed, biopharmaceuticals are characterized by large molecular sizes and various levels of structural complexity (i.e., primary, secondary, tertiary, or

quaternary), which render them particularly vulnerable to various forms of degradation or denaturation. Most current strategies for formulating biopharmaceuticals into appropriate dosage forms or delivery systems are aimed specifically at preserving the structural integrity and biological activities of these complex macromolecules as well as at improving their bioavailability or targeting them to specific sites in the body. Presented below is a general discussion on the formulation of biopharmaceuticals with particular emphasis on the techniques using pharmaceutical excipients or additives to achieve these aims. Biotechnological techniques that use viral vectors to deliver genes or nucleic acid-based drugs are outside the scope of the current discussion.

4.3.5.1 Protein and Peptide Drugs

With the aid of newer production techniques, such as recombinant DNA technology and transgenic protein production, coupled with cost-efficient protein purification techniques, proteins of high purity can now be mass-produced for therapeutic uses.

In protein production, selection of the host cells (e.g., bacterial, yeast, or mammalian cells) for the expression of recombinant proteins is critical, as this will determine the chemical properties (e.g., amino acid sequence/composition and glycosylation) as well as the pharmacokinetic behavior, biological activities, and potential toxicities of the resulting proteins [176]. For instance, granulocyte macrophage colony stimulating factor (GM-CSF) expressed in *Escherichia coli* bacteria is a glycosylated form with six fewer amino acids and one more methionine residue than the non-glycosylated native protein [177, 178]. Although both yeast and mammalian expression systems can produce glycosylated proteins, only the mammalian system can generate the more complex carbohydrate moieties, which may be associated with higher immunogenicity. In addition, various types of contaminants (e.g., viruses, toxins, and nucleic acids) may arise during the production, and thus establishment of the protein purity at the initial stage of formulation development is of paramount importance [179, 180].

A challenge to develop a high-concentration protein formulation is perhaps the limited solubility of the protein in aqueous solution. The aqueous solubility of a protein is governed by the interaction of its polar residues with water, whereas the non-polar side chains and peptide groups are normally buried in the folded protein to maintain the native state. In general, minimum protein solubility occurs at the isoelectric point (*p*I), where the protein molecule acquires a net-zero charge [181]. Thus, to ensure adequate solubility in water, proteins should not be buffered at or near their *p*Is. However, when selecting an appropriate pH for the vehicle, considerations should also be given to the chemical integrity and activity of the proteins, as these are also pH-dependent.

Proteins are amino acid chains that fold into unique three-dimensional structures. The primary structure of proteins is the peptide sequence of the whole molecule, which can be characterized by the amino acid composition, N-terminal amino acid sequence, C-terminal amino acid sequence, and peptide mapping.

The secondary structure refers to the general three-dimensional local regions of the protein, encompassing regions of α-helices, β-sheets, and supersecondary

structures. Such local structures can be analyzed by circular dichroism, Fourier transform infrared spectroscopy, and fluorescence spectroscopy.

The tertiary structure refers to the overall three-dimensional structure of the polypeptide units of a given protein. Just as the secondary structure may be conceptually linked to distinct domains within a protein, the tertiary structure can be associated with the way by which these domains are related to one another. Interactions among such domains are governed by various physical forces, including hydrogen bonding as well as hydrophobic, electrostatic, and van der Waals interactions. The tertiary structure of proteins can be determined using a combination of analytical and complementary computer-aided modeling techniques, including solution nuclear magnetic resonance (NMR) spectroscopy, single-crystal x-ray crystallography, neutron diffraction, and molecular dynamics simulation.

In general, no single analytical technique can be used to fully characterize biopharmaceuticals. Aside from structural characterization, functional analyses, including immunoassay and bioactivity assay, are also essential for ascertaining the quality of biopharmaceuticals. Although immunoassay is more specific than bioassay in the presence of interfering factors, the data derived from the two techniques may not show any direct correlation with each other, mainly because the former detects not only biologically active proteins, but also denatured proteins and fragments as well as inactive protein-receptor complexes [182]. Some commonly used protein characterization techniques are summarized in Table 4.3-1. More specific reviews on protein and peptide analysis are presented elsewhere [183, 184].

An appropriate choice of excipients is also an important consideration in protein/peptide formulation, as it can profoundly influence the shelf-life, pharmacokinetic behavior, and efficacy of the final products. Table 4.3-2 shows a list of excipients commonly used in protein/peptide formulation [185]. Extensive reviews on excipient selection are available in literature [186, 187]. In general, excipients are experimentally selected by screening [188, 189]. The selection is guided by their abilities to produce the desired outcomes for the final dosage forms. For example, the stability of hybrid interferon-α in solution, which is sensitive to both pH and buffer composition, can be improved by adding mannitol or lactose at pH 4.0 [190]. However, at pH 7.6, lactose exerts an accelerating effect on the degradation of interferon-α, suggesting that an optimal pH exists for the excipient to function as a stabilizer. In another study, hydroxypropyl-β-cyclodextrin has been shown to effectively protect β-galactosidase against degradation during spray-drying [191]. Apart from the type of excipients used, the physical form of the excipients is also critical for the stabilization of proteins. For instance, mannitol in the amorphous state can preserve the structure and prevent the aggregation of recombinant humanized anti-IgE monoclonal antibody [166].

As many excipients are capable of stabilizing proteins under different conditions, it is unlikely that the stabilization effect is excipient-specific. It is widely believed that the stabilizing mechanism of excipients involves the preferential exclusion of the added excipient from the protein in aqueous solution and during freeze–thawing [192]. Briefly, a protein in an aqueous environment is in dynamic equilibrium between the native and the denatured (unfolded) forms. As the exclusion of excipient from the unfolded form is greater than that from the native form, the equilibrium will shift toward increasing concentration of the native form. Thus, the unfolding of protein in the presence of excipient is a thermodynamically

TABLE 4.3-1. Summary of the Commonly Used Analytical Techniques for Protein/Peptide Characterization

Technique	Principle	Application	References
Colorimetric analysis	Based on specific chemical reaction and associated color change	Quantitative analysis; BCA assay	[207]
High pressure liquid chromatography (HPLC)			[226]
Reversed-phase chromatography (RPC)	Separation by hydrophobicity	Quantitative, stability (aggregation), purity analysis	
Size exclusion chromatography (SEC)	Separation by size (larger molecule elutes faster)		
Ion-exchange chromatography (IEC)	Separation by electrostatic interaction		
Electrophoresis			[227]
SDS-PAGE	Separation based on molecular sieving by gel matrix	Size, purity, stability analysis	
Capillary electrophoresis (CE)	Electrophoretic separation on capillary	Peptide analysis, purity, stability analysis	
Isoelectric focusing (IEF)	Separation based on continuous pH gradient (proteins migrate according to charge properties until the point of zero charge, i.e., isoelectric point or pI, is reached.)	Purity analysis, pI determination	
Mass spectrometry (MalDI-TOF)	Separation based on mass-to-charge ratio (m/z) in magnetic or electric field	Quantitative analysis (high sensitivity) Identification and integrity	[228, 229]
Immunochemical analyses			
Enzyme-linked immunosorbent assay (ELISA)	The first antibody is coated onto plastic surface and conjugated with antigen, whereas the second antibody is coupled to an enzyme; detection by color change of a chromogen when it is cleaved by the enzyme	Quantitative analysis; epitope quality	[207]
Bioassay	Based on biological effects of proteins (e.g., cell proliferation, cytotoxicity, and antiviral activity.)	Quantitative analysis; potency test	[230–231]

TABLE 4.3-2. Excipients Commonly Used to Stabilize Biopharmaceuticals (from Ref. 185)

Excipient Type	Examples
Amino acids	Glycine, arginine, alanine, proline, aspartic acid, glutamic acid, lysine
Sugars	Trehalose, sucrose, maltose, fructose, raffinose, lactose, glucose
Surfactants	Poloxamer 407, Poloxamer 188, polysorbate 80, polysorbate 20, octoxynol-9, polyoxyethylene-(23) lauryl alcohol, polyxyethylene-(20) oleyl alcohol, sodium lauryl sulphate
Salts	Sodium sulphate, ammonium sulphate, magnesium sulphate, sodium acetate, sodium lactate, sodium succinate, sodium proprionate, potassium phosphate
Polyols	Cyclodextrins, mannitol, sorbitol, glycerol, xylitol, inositol
Antioxidants	Ascorbic acid, glutathione
Polymers	Polyethylene glycol, dextran, polyvinylpyrrolidone
Chelating agents	EDTA, tris(hydroxymethyl)aminomethane (TRIS), diethylenetriaminepentaacetic acid, inositol, hexaphosphate, ethylenediaminebis (O-hydroxyphenylacetic acid), desferal

unfavorable process. This is to be expected because the excipient would denature the protein if it were to bind favorably to the exposed hydrophobic sites of the unfolded protein.

Two nonexclusive mechanisms, namely, glass dynamics hypothesis and water substitution concept, have also been proposed to explain the stabilization effects of excipients during the dehydration stage in freeze-drying [193]. According to the glass dynamics hypothesis, freeze-dried excipients form a rigid, amorphous, inert matrix where the dispersed protein molecules have limited mobility, being restricted from undergoing arrangement and eventual phase separation. Therefore, stabilization is via a kinetic mechanism and would be expected to correlate with the molecular mobility in the rigid matrix. The water substitution theory suggests that the stabilization effect is due to the substitution by the excipient for water to maintain hydrogen bonds with surface-accessible polar sites on the protein. Such interaction facilitates the preservation of the native-like solid-state protein structure and may help reduce the tendency of the protein molecules to form aggregates during storage. These stabilization mechanisms have been reviewed in depth by Pikal [194].

Most commercial protein/peptide products are administered by the parenteral route (e.g., subcutaneous, intramuscular, or intravenous) in the form of injections. The major disadvantages of parenteral injections are the inconvenience to the patient, high cost, and poor patient compliance. To overcome these problems, alternative administration routes such as peroral [195, 196], buccal [197], pulmonary, nasal [198], and transdermal [199] routes have been considered. However, nonparenteral protein delivery also suffers certain drawbacks, most of which are related to the inherent physicochemical characteristics of the proteins, including their large molecular size, low lipid membrane permeability, susceptibility to enzymatic degradation, potential immunogenicity, and bio-incompatibility as well as the propensity to undergo aggregation, adsorption, and denaturation. Not all

nonparenteral routes share these limitatons. For instance, absorption via the buccal mucosa is free from degradation by protease activity and allows the absorbed protein to bypass the liver to gain direct entry into the systemic circulation, thus avoiding the first-pass hepatic metabolism. Pulmonary delivery also offers a similar advantage of bypassing the first-pass effect.

The feasibility of protein delivery via different routes of administration is best illustrated by insulin, a well-characterized and extensively studied therapeutic protein. To date, attempts to exploit the nasal, oral, and transdermal routes for insulin delivery have not been very successful for reasons related mostly to the stability and efficiency of delivery [200]. For instance, oral insulin delivery is subject to activity loss due to the acidity in the stomach and the presence of proteases and peptidases in the gut. Moreover, the intestinal absorption of the protein is limited by its large molecular size and hydrophilic nature. Various specific strategies to overcome these delivery barriers have been attempted, including the use of permeation enhancers, protease inhibitors, and enteric-coated microsphere formulations [201]. As an alternative solution to these problems, the pulmonary route has also been extensively investigated for its utility in protein delivery [202]. As has been well documented, lungs have a large surface area, which allows rapid drug absorption due to the close contact between the alveoli in the deep lung and the systemic circulation. As a result of intense formulation research, a novel inhalation insulin product by the commercial name, Exubera, was developed and subsequently approved by the Food and Drug Administration (FDA) Advisory Committee Panel in September 2005 for the treatment of adult type 1 and type 2 diabetes. The product is a rapid-acting, dry powder form of insulin derived through rDNA. The main concern with inhaled insulin products is the potential long-term adverse effects resulting from the intra-alveolar deposition of insulin within the lung, because insulin has growth-promoting properties. It can be envisaged that once long-term safety and efficacy is established, inhalation may become the first nonparenteral route used clinically for insulin delivery.

Apart from the aforementioned problems with oral delivery, certain undesirable pharmacokinetic properties of proteins, notably the short biological half-life, have presented additional hurdles in their formulation development. To lengthen the biological half-life and prolong the action of proteins in the body, several novel drug delivery strategies have been developed through chemical modification of the protein molecule (e.g., pegylation) or new formulation development (e.g., controlled or sustained release formulation).

Pegylation, defined as the chemical process by which polyethylene glycol chains are attached to protein and peptide drugs, have been successfully applied to produce peginterferon alfa-2a (PEGASYS) and peginterferon alfa-2b (PEG-Intron), both of which have been approved by the FDA for the treatment of chronic hepatitis C [203].

Another approach to extend the action of proteins is to develop biodegradable polymeric microspheres. Owing to their excellent biocompatibility, the biodegradable polyesters, poly(lactic acid) (PLA) and poly(lactic-co-glycolic acid) (PLGA), are the most frequently used biomaterials to achieve sustained action [204, 205]. Polymeric microspheres are commonly prepared by the solvent extraction/evaporation methods [206]. In brief, protein in a solid or liquid form is mixed with a polymer (dissolved in an organic solvent, e.g., dichloromethane) to prepare a solid-

in-oil or water-in-oil emulsion. The resulting emulsion is further mixed with water containing an emulsifier (e.g., polyvinyl alcohol) to effect protein loading into the PLGA microspheres [207]. Release of protein from such microspheres usually occurs in three phases, namely, initial burst release, diffusion-controlled release, and erosion-controlled release.

The intrinsic drawbacks with these microencapsulation methods are that the organic solvents used and the low pH generated inside the matrix due to PLGA degradation may denature the protein. As an alternative for these biodegradable polyesters, hydrogels, which are prepared from natural or synthetic hydrophilic polymers, have been evaluated for use as protein-releasing matrices either alone or in combination with PLGA (i.e., as composite microspheres). Using the latter approach, a novel sustained-release insulin formulation has been developed by incorporating insulin into the hydrogel to yield microparticles, followed by encapsulation in a PLGA matrix as microspheres [208]. The swelling behavior of hydrogels, which governs drug release, is dependent on the external environmental conditions, such as temperature and pH. Hydrogel-based delivery devices can be used for oral, rectal, ocular, epidermal, and subcutaneous application. Excellent reviews on this topic can be found in literature [209, 210].

In general, proteins are more stable in the solid state than in the liquid state. A variety of methods are available for preparation of protein powders, including precipitation, lyophilization, and spray-drying. The main concern with these methods is the potential protein denaturation or inactivation during the preparation. More specialized techniques for preparing protein materials with specific applications have also been developed, such as supercritical fluid processing for human growth hormone [211], spray-drying for producing inhaled insulin [212], spray–freeze-drying into liquid to produce stable bovine serum albumin (BSA) nanostructured microparticles [213], supercritical fluid-based coating technology to produce lipid coated BSA particles [214], and emulsion precipitation [207]. Maa and Prestrelski [215] have presented a systematic review on protein powder production techniques. Table 4.3-3 shows a comparison of the advantages and disadvantages of these powder preparation methods. For assessment of the utility of these techniques, it is important that the resulting powders be subjected to rigorous physical and chemical characterization, including crystal form, particle morphology, particle size distribution, surface properties, and moisture content [212].

4.3.5.2 Nucleic Acid-based Drugs

Nucleic acid-based drugs also represent an important group of biopharmaceuticals that are still at their very early stage of development. Nucleic acids are complex, and high-molecular-weight macromolecules composed of nucleotide chains that convey genetic information. The most common nucleic acids are DNA and RNA. RNA is usually single stranded, whereas DNA is normally double stranded and can form a double helix via hydrogen bonding. Single-stranded RNA molecules tend to associate with one another via hydrogen bonding to attain the minimum energy state. DNA and RNA can be characterized for primary sequence by biochemical techniques [e.g., Southern blotting and polymerase chain reaction (PCR) for DNA and Northern blotting and reverse transcription-PCR (RT-PCR) for RNA]. They can also be analyzed in very much the same way as proteins by spectroscopic and

TABLE 4.3-3. Advantages and Disadvantages of Different Powder Preparation Methods (from Ref. 215)

Method	Advantage	Disadvantage
Freeze-drying	High yield; convenient operation; aseptic process; expensive process	Poor particle size control; irregular-shaped particles; broad size distribution
Spray-drying	Good particle size control; spherical-shaped particles; easy and convenient operation	Yield dependent on formulation; heat inactivation; surface denaturation
Spray–freeze-drying	Good particle size control; spherical-shaped particles; high yield; good aerosol properties	Poor density control
Supercritical fluid	Good particle size control; spherical-shaped particles	Complex process; limited solubility in organic solvents
Pulverization	Easy operation; high yield	Poor particle size control; irregular-shaped particles; broad size distribution
Precipitation	Simple and convenient operation; high yield	Poor particle size control; irregular-shaped particles; broad size distribution; protein denaturation; difficult to handle multicomponents
Emulsification followed by precipitation	Easy to control; particle size <3 μm; spherical-shaped particles; applicable to a variety of materials	Yield limited by solubility; protein denaturation by organic solvent; difficult to handle multicomponents

chromatographic techniques, including ultraviolet, infrared, Raman, fluorescence spectroscopy, circular dichroism, NMR, mass spectrometry, and HPLC [46].

Nucleic acid-based therapeutics aims to deliver nucleic acid-derived products into the nuclear compartment, which may act at the molecular genetic level either to replace a defective gene or to modulate a specific genetic function. Six types of nucleic acid-based therapeutics have been proposed, namely, antisense (molecules that interact with complementary strands of nucleic acids and modify expression of genes), ribonucleic acid inhibition (RNAi), gene therapy (insertion of genes into an individual's cells and tissues to treat a disease, particularly hereditary diseases), nucleoside analogs, ribozymes (RNA enzymes or catalytic RNAs that catalyze chemical reactions), and aptamers (DNAs or RNAs that are selected from random pools based on their ability to bind nucleic acids, proteins, or small organic compounds). Only one antisense drug named fomivirsen (Vitravene® developed by Isis Pharmaceuticals, Carlsbad, California) has been approved by the FDA for the treatment of cytomegalovirus retinitis and is currently available in the clinic, whereas others are still under development.

Compared with other organic drugs, nucleic acids are relatively large, hydrophilic, and negatively charged molecules. Systemic delivery of nucleic acids targeted at the nuclear compartment is limited by the hostile extracellular environment, including extreme pH, degradation enzymes (proteases and nucleases), as well as the immune defense and scavenger systems. Lechardeur et al. [216] have summarized the major cellular, metabolic, and physico-chemical barriers to the delivery of plasmid DNA into nucleus. A series of strategies employing physical forces (e.g., microinjection, naked DNA injection, electroporation, and gene gun), nonviral gene carriers (e.g., cationic liposome or cationic polymers), and/or biological carriers (e.g., viral gene carrier) have been developed to deliver nucleic-acid-derived drugs into cells [217]. Viral gene carriers, which rely on cell infection by live (nonpathogenic) viruses (e.g., adenovirus) to achieve specific site targeting, may cause severe immune response in the patient, and their delivery is limited by the gene size, which can be accommodated by the viral genome. Nonviral gene medicine is composed of three elements: a gene encoding a therapeutic protein, a plasmid-based gene expression system that controls the function of a gene within a target cell, and a synthetic gene carrier that controls the stability and gene delivery within the body. The most extensively investigated synthetic gene carriers involve the combination of plasmid DNA with either cationic lipids (lipoplexes) or polymers (polyplexes), or in association with encapsulation into microspheres or preparation of nanoparticulate systems.

Lipoplexes are prepared by the interaction of anionic nucleic acids with the surface of cationic lipid to afford multilamellar lipid–nucleic acid complexes. Cationic liposomes can protect nucleic acids from serum nucleases and facilitate the cellular uptake and release of nucleic acids into the cytosol [218]. Pedroso et al. [219] have extensively discussed the structure-activity relationships of cationic liposome/DNA complexes and the key formulation parameters influencing the properties of lipoplexes. In addition, optimization of the cationic liposomal complexes for *in vivo* application has been reviewed by Smyth [220].

Polyplexes are formulated by condensation of negatively charged nucleic acids via electrostatic interactions with polycationic condensing polymers to yield compact particles, which can then protect the nucleic acids and mask the negative DNA charges. The polycations used include natural DNA binding proteins such as histones, synthetic polymers such as poly[dimethylaminoethyl-methacrylates], linear or branched polyethylenimine, diethylaminoethyl modified dextran, or modified chitosan. The physico-chemical and biopharmaceutical behaviors of these polymers in nucleic acid delivery have been extensively reviewed elsewhere [221, 222]. Besides these polymers, polyethylene glycol-conjugated copolymers have also been introduced as an alternative drug carrier material [223]. However, these polyplexes are incapable of affording sustained release for nucleic acids and prolonging gene transfer. To achieve prolonged action of nucleic-acid-based drugs, the feasibility of encapsulating polyplexes into certain matrices to obtain sustained-release nanoparticles or microparticles is currently under investigation. Yun et al. [224] have prepared microspheres by physically combining poly(ethylene glycol)-grafted chitosan with poly(lactide-co-glycolide) using a modified conventional in-emulsion solvent evaporation method to achieve prolonged delivery of DNA/chitosan polyplexes.

Nanoparticles are submicronic (less than 1 μm) colloidal systems, which can be classified into two main categories depending on whether the formation of

nanoparticles requires a polymerization reaction. Nanoparticulate systems have been developed to deliver antisense oligonucleotides with enhanced stability and delivery efficiency [225].

4.3.6 SUMMARY AND CONCLUSIONS

Biopharmaceuticals constitute a unique class of therapeutic agents that are difficult to handle and process because of their structural complexity and inherent chemical/physical instability. Depending on the modes of chemical degradation or physical denaturation, a wide variety of formulation excipients or additives, including buffers, antioxidants, sugars, and polysaccharides, can be employed to preserve the structural integrity and biological activity of such vulnerable macromolecules. In addition, an appropriate choice of administration route is critical for maximizing their bioavailability and efficacy. Sustained or prolonged action for specific therapeutic indications has also been made possible by formulating them in synthetic polymeric carriers, including biodegradable polymers, hydrogels, and polycationic polymers. It can be envisioned that as more is known about the relationship between the structures and the bioactivities of these vital macromolecules, the existing formulation strategies can be further improved or fine-tuned for particular biopharmaceuticals to achieve more promising therapeutic outcomes.

4.4.1 INTRODUCTION

Protein posttranslational modification (PTM) is a hallmark of signal transduction and it allows the cells to rapidly respond to extracellular signals. In most cells, only a fraction of the genes are turned on at any given time, producing no more than 6000 primary proteins in a process called translation. However, several hundred types of PTMs could occur, greatly amplifying the diversity of proteins present in the cells [1]. These modifications, which involve stable and, sometimes, irreversible additions of nonamino acid chemical groups to primary translation products, occur in a large proportion of the cellular protein pool. In some instances, the types of PTMs of a protein can be predicted from its primary sequence. In many cases, however, such predictions are not possible. These modifications can result in an enormous amplification of the diversity of a protein pool. For example, glycosylation, the addition of sugar chains of varying lengths and compositions of one unmodified protein at three sites, can generate 11,520 protein variants. PTM of a protein is predicted to generate a combinatorial effect on protein structure and functions [2, 3]. The known PTMs include phosphorylation, acetylation, methylation, glycosylation, oxidation, sumoylation, ubiquitination, and nitration [4–10]. PTM of core histone proteins has been widely studied in the context of chromatin structure and gene transcription [11]. However, PTM of nonhistone proteins has only recently begun to receive attention [12–15].

This chapter will be focusing on several important issues in PTM studies such as:

- Why the proteins need to be modified and how they are modified.
- The relationship between prokaryotic and eukaryotic PTMs.
- Basic tools for studying PTM and the recent advancement in facilities and resources.
- PTM and signal transduction by nuclear receptors, co-regulators, and transcription factors.
- PTM as a target in rational design and development of therapeutic agents.

4.4.2 WHAT IS PROTEIN POSTTRANSLATIONAL MODIFICATION?

Simple Definition. The primary structure of a protein is dictated by its genetic code. All the proteins from the genome constitute the “proteome.” After translation, the proteome is covalently modified by a variety of small molecules of exogenous or endogenous origin, and also by other proteins or peptides. The event is defined as the “protein posttranslational modification.”

Studies of proteins present in a cell revealed a rich repertoire of expressed proteins way beyond what is expected from direct translation of the messages produced by a genome. Proteins can be modified posttranslationally by covalent attachment of one or more of several classes of molecules, by the formation of intramolecular or intermolecular linkages, by proteolytic processing of the newly synthesized polypeptide chain, or by any combination of these events. These modifications endow a protein with various properties that may be specifically required under a particular condition.

4.4.3 OVERVIEW OF PROTEIN POSTTRANSLATIONAL MODIFICATION

The most common PTMs include:

- *Glycosylation*—the addition of one or more sugar molecules to asparagine (N-linked) and Ser/Thr (O-linked) residues, which may involve more than one type of sugar, as shown in estrogen receptor (ER) [16] and androgen receptor (AR) [17].
- *Phosphorylation*—the addition of phosphate groups to Ser/Thr and Tyr residues, as shown in receptor interacting protein 140 (RIP140) [4], orphan testicular receptor 2 (TR2) [18], retinoic acid receptor (RAR) [19], and retinoid X receptor (RXR) [19].
- *Myristoylation and Prenylation*—the addition of certain fatty acids as shown in G-protein coupled receptor (GPCR) [20] and estrogen receptor (ER) [21].
- *Acetylation*—the addition of acetate groups to lysine residue as shown in nuclear receptors [22, 23], p53 [6], NF-κB [24], and histone proteins.
- *Methylation*—the addition of methyl groups to Arg/Lys/Gln/Asn (N-methyl) and Ser/Thr (O-methyl) as shown in p53 [25], PGC-1α [13], CBP/p300 [26], and YY1 [27].
- *Ubiquitination*—the addition of one or more ubiquitin molecules to proteins, which marks the protein for degradation as shown in p53 [28].
- Addition of a prosthetic group (e.g., heme in hemeproteins, such as hemoglobin), which is required for the protein's function).
- Addition of a certain chemical bond (i.e., a disulfide bond) between two sulfur-containing amino acids.
- Addition of a target leader sequence (a small removable peptide) at the beginning of the protein chain to allow the protein to be targeted to or from subcellular organelles (e.g., nuclei and mitochondria).

4.4.4 WHY THE PROTEINS NEED TO BE MODIFIED?

Proteins sometimes need to be modified to become functional. Secondly, the functional diversity of a protein can be greatly amplified by different posttranslational modifications. Modification of protein can dramatically alter its physico-chemical properties (i.e., hydrophobicity, stereochemical structure and conformation, and protein stability). Phosphorylation and glycosylation make a protein more hydrophilic, whereas acetylation, methylation, and prenylation are generally known to increase hydrophobicity of the protein. Ubiquitination typically functions as a tag for the proteins, which could be recognized by proteases (proteosomes) for degradation. Reactive oxygen species can oxidize cystein and methionine, whereas nitric oxide can react with cystein and tyrosine residues. These modifications can also modulate the function of the protein by influencing processes such as protein–protein interaction, transport, and stability.

4.4.5 PROKARYOTIC VERSUS EUKARYOTIC PTM

It is generally believed that proteins are not posttranslationally modified in prokaryotic cells with some exception for glycosylation of the membrane protein, which is essential for the membrane integrity and virulence property of many bacteria. However, recent investigation showed that prokaryotic proteins could also be modified, such as by phosphorylation. Some prokaryotic protein kinases, which were evolutionarily related to kinases of the eukaryotes, were discovered [29]. It was also speculated that bacterial protein could be modified by methylation, as shown by metabolic labeling using radioactive S-adenosylmethionine. Methylation was shown to enhance the chemotaxic response of the bacteria as well as the sensory transduction in *E. coli* [30]. Thus, prokaryotic proteins could also be modified to enhance their functional diversity. Our recent investigation using mass spectrometry-based proteome analyses of nuclear co-regulator RIP140 expressed from bacteria also revealed that proteins expressed in bacteria can be modified by methylation at asparagine (N) and arginine (R) (Huq and Wei, unpublished result).

It has become increasingly clear that PTM can also occur in *Archaea*. *Archaea* express proteins that enable them to strive in harsh habitats. Archaeal proteins are able to remain properly folded and functional under extremely harsh conditions such as high salinity and temperature, and other adverse physical conditions that would normally cause protein denaturation, loss of solubility, and aggregation [31].

4.4.6 STUDIES OF PTM

Studies of PTM have been benefited from the recent advancements in mass spectrometry, the introduction of new software and Internet-based MS data search facilities, computer-assisted topology prediction for a variety of PTMs (visit http://ca.expasy.org/), chemical synthesis of modified peptides and proteins, development of modified peptide specific antibody, *in vitro* modification techniques, exploitation of other eukaryotic cells such as insect cells for protein expression [4, 5, 16, 32], and progress in affinity purification of modified proteins.

4.4.6.1 Mass Spectrometry-based PTMs

Mass spectrometry has revolutionized the idetinification of PTM. In the past, the metabolic radio-labeling technique was the principal methodology used to determine whether the protein is modified. However, identification of a specific residue that is modified by PTM using metabolic labeling relies on point mutation of the protein, which is practically time- and effort-consuming and sometimes unreliable because of existance of other similar sites of PTM [33]. The mass spectrometric analysis can identify all kinds of modification on a protein in a single experiment. However, sometimes it can be a laborious and lengthy process because of the need to purify the protein. Data analysis itself can also be time-consuming. We will use several MS-based PTM analyses in our own experiences as examples just to illustrate the design and execute the entire experiment.

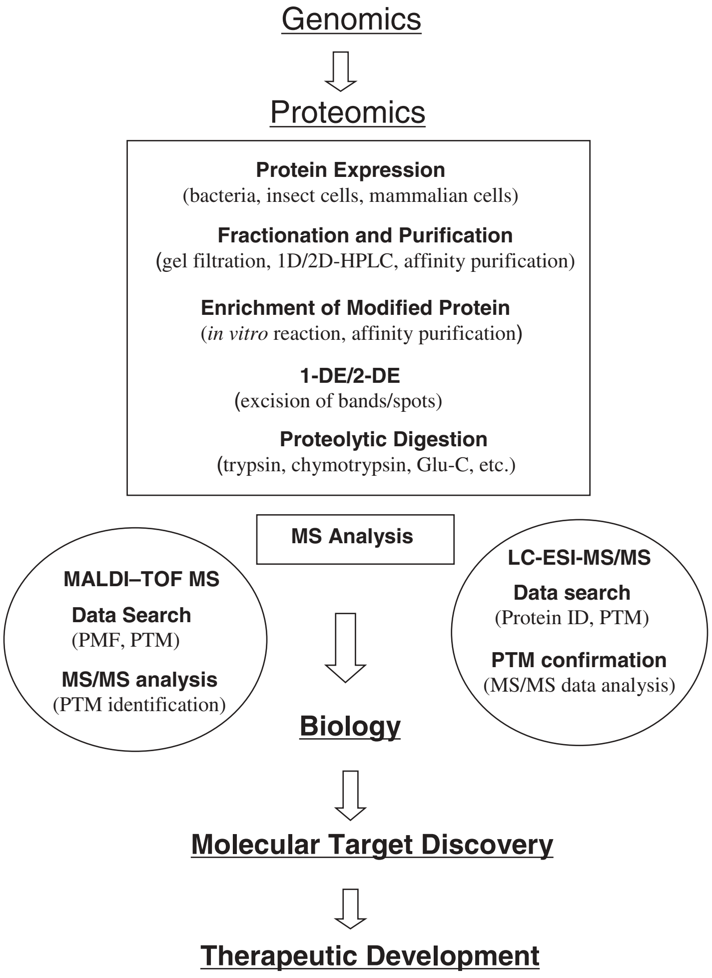
- *Sample.* The type of protein (i.e., membarne, cytosolic or neuclear protein) the pI value, the molecular weight, the solubility and stability. The amino acid sequence of the protein needs to be considered, which is necessary for the selection of proper proteases for proteolytic digestion.
- *Sample Preparation.* Sample preparation is the most critical step in mass analysis. The prurifacation procedure and the presence of potentially interfering substance for MS should be evaluated. For instance, the type and the concentartion of detergent used for solubilizing the protein may not be compatibe with mass spectrometry.
- *Type of Modifications.* The specific chemistry of the type of modification and its stability during the procedure.
- *Sites of Modification (residues).* The residues (amino acid) where the modification could occur, such as Arg/Lys for methylation, Ser/Thr or Tyr for phosphorylation, Tyr or Cys for nitration. The sites of modification is also important because it may interefer with protease digestion of the protein. Selection of the protease sometimes depends on the location of the sites of modification.
- *Mass Spectrometry Facilities.* The facilites of mass spectrometry (i.e., MALDI–TOF, MALDI–TOF–MS/MS, LC–MS, LC–ESI–MS/MS) and other resources for data search and management. In most cases, each machine is designed for a particular purpose.
- *Knowledge and Training.* It is crucial to acquire adequate working knowledge about mass spectrometry in addition to understanding the principle. It is also important to receive hands-on training in the operation of MS database search and manual data interpretation skills to verify the PTM and PTM sites, which is particularly critical to accurately interpret the data and to avoid any false-positive or fasle-negative result.

  These points are presented in Scheme 4.4-1.

A practical, step-by-step guideline for successful studies of PTM is provided based on our own experience in studying PTMs of several transcription regulatory proteins including RIP140, RAR, RXR, TR2, TR4, and NF-κB.

Step 1. Determine the types of modification to be examined. It would be useful to gather information on whether this type of modification can be enriched. For example, enzymatic induction, *in vitro* chemical reaction, and expression of protein in suitable eukaryotic (i.e., insect cells) or prokaryotic systems. Some commercial products for enrichment of modified peptides such as phosphopeptides are currently available (visit Ionsource website at http://www.ionsource.com/ for more information about this option).

Step 2. Purify the protein in a system in which the modification is stable. Avoid any kind of external contamination during purification, for example, keratin, which is the most common impurity present in MS analysis. If purification is not possible, it can be enriched, separated, and recovered from an SDS–PAGE. The amount of sample is also important. A very sensitive machine can identify the protein at the famtomole level.



Scheme 4.4-1. Strategies and goal of proteome analysis.

Step 3. Carry out theoretical digestion of the protein to select proteases (i.e., trypsin, chymotrypsin, and Glu-C) using software available online (http://ca.expasy.org/ and MS–DIGEST at http://prospector.ucsf.edu/). Analyze the theoretical mass of each peptide and select the proper protease for digestion that will give you the maximum coverage of the protein with the molecular weight of each peptide no more than 3000 Da. However, most of the researchers select trypsin initially.

Step 4. Run a 1-DE/2-DE gel and stain the gel by commassie blue. Silver-stained gels need extra steps in destaining. All operation should be carried out in a dust-free envrionment to avoid contaminants like keratin. Staining or destaining solution and PAGE running buffer should not be recycled. Excise the protein band of interest and conduct in gel digestion. In-solution tryptic digestion can also be done. However, most investigators prefer in-gel digestion. Several protocols for in-gel digestion on commassie-stained and silver-stained gels are available online at the

University of Minnesota proteomics core facilities website (http://www.cbs.umn.edu/msp/).

Step 5. Desalt the tryptic peptides using ZipTip (Millipore). The ZipTip protocol is also available online (http://www.cbs.umn.edu/msp/) and spotted on a MALDI target over the crystal of matrix molecule (i.e., α-cyano-4-hydroxycinnamic acid). The full-scan spectrum is recorded and the peak lists are generated by software. The experimental mass value (monoisotopic) from the peak lists could be copied and pasted to the Mascot peptide mass fingerprint data search (http://www.matrixscience.com/) or MS-fit data serach (http://prospector.ucsf.edu/) for peptide mass fingerprinting (PMF) to identify the protein of interest or verify the protein identity. The search result will show the identified protein according to the match of mass of a number of peptides, their scores, and the sequence coverage of the total protein. An overview about PMF is described below, which is also available at Ionsource website as tutorials (http://www.ionsource.com/). When the protein is properly identified, the investigator can look at the original mass spectrum and compare with the mass data of theoretical digestion and subtract the peak manually from the full-scan MALDI spectrum one by one. The remaing peaks in the spectrum could originate from the PTM-modified trypsin autolysis peaks or contaminants. If the spectrum is of high quality, the investigator can analyze each individual peak and the neighboring peaks to determine the mass shift between the neighboring peaks, providing some insights into whether the protein is modified. An important consideration is that the modification should be stable or suitable for ionization by MALDI. If the mass shift between the two neighboring peaks give a mass shift equal to the mass shift caused by modification (i.e., 80 amu for phosphorylation and 42 amu for acetylation), that particular ion peak is likely to be originated from the modified peptide. To confirm this modification, the MS/MS spectrum of that parent ion can be recorded from the same sample spotted on a different target.

Peptide Mass Fingerprinting. PMF is an important tool to identify proteins by matching their constituent fragment ions (peptide masses) to the theoretical peptide masses generated from a protein or DNA database. The conceptual basis of PMF is that every unique protein generates a unique set of peptides and hence unique peptide masses. An intact unknown protein is first cleaved with a proteolytic enzyme to generate peptides. A PMF database search is conducted following MALDI–TOF mass analysis of the protein sample. Identification is accomplished by matching the observed peptide masses to the theoretical masses derived from a sequence database. PMF identification relies on observing a large number of peptides (5 or more) from the same protein at high mass accuracy. This technique is particularly suited for 1D/2D gel spots where the protein purity is high. However, it is less efficient for complex mixtures of proteins.

Although this technique was introduced in early 1990s, it was the introduction of a MALDI–TOF instrument capable of 50 ppm mass accuracy that made PMF a routine procedure. In MALDI–TOF mass spectrometry, peptides appear as singly charged species in the mass spectrum (Figure 4.4-1). Unlike an electrospray (ESI) mass spectrum, which displays multiply charged species, the MALDI–TOF spectrum is simple to interpret. PMF can also be used to identify proteins in ESI spectra, but it is seldom used because the peptide masses would need to be deconvoluted for each search.

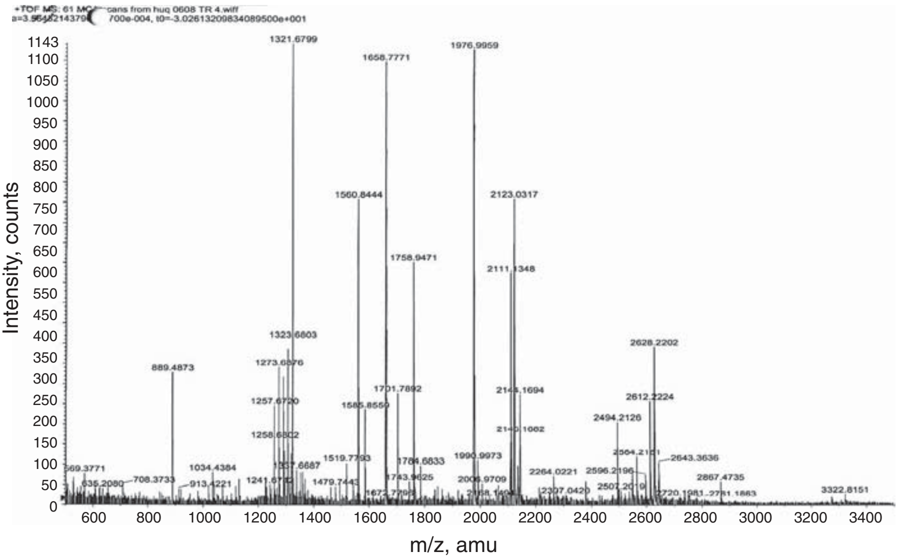


Figure 4.4-1. MALDI–TOF mass spectrum of orphan nuclear receptor TR4. This was collected on a QSTAR-XL MALDI–TOF mass spectrometer and was an average of 240 scans; peptide peaks appear as $[M+H]^{1+}$ ions.

LC–ESI–MS/MS analysis. To examine the potential PTM of a protein after MADLI–TOF mass, a liquid chromatography-tandom mass spectrometry (LC–ESI–MS/MS) is run to obtain information-dependent acquisition (IDA) data. Alternatively, an LC–ESI–MS/MS analysis can be performed without prior MALDI–TOF. However, it is the most common practice to first conduct a MALDI–TOF mass to determine the amount of sample to be loaded on a subsequent LC–ESI–MS/MS. The IDA data could then be searched at Mascot MS/MS data search (available online at http://www.matrixscience.com/) by selecting several parameters, such as protein data bank (i.e., NCBI and MSDB), the species, the fixed modification (i.e., carbamidomethyl cystein), the variable modifications, and the mass tolerance. The search result will generate information about the protein. The reconstructed MS/MS spectrum along with the calculated mass value of product ions matched in the original MS/MS spectrum can be obtained, which will show the residue modified by PTM. To confirm the modification, manual analysis of the MS/MS data is essential.

MS/MS Fragmentation and Nomenclature. The fragmentation pattern and the nomenclature commonly used in MS/MS studies are discussed below. This information was taken from Mascot website (http://www.matrixscience.com/).

Sequence Ions. The types of fragment ions observed in an MS/MS spectrum depend on many factors including primary sequence, the amount of internal energy, how the energy was introduced, and the charge state. The MS/MS fragmentation pattern is shown in Chart 4.4-1.

Fragments will only be detected if they carry at least one charge. If this charge is carried by the N-terminal fragment, the ion is called either *a*, *b*, or *c*. If the charge

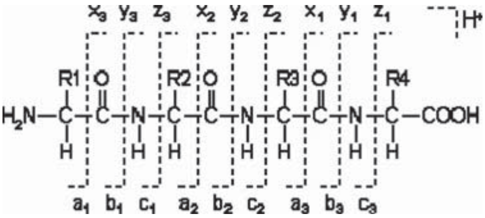

Chart 4.4-1.

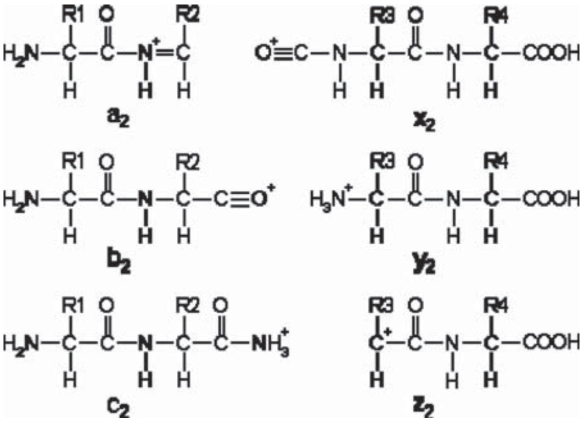

Chart 4.4-2.

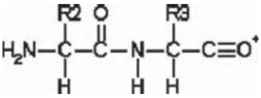

Chart 4.4-3.

is retained on the C-terminal fragment, the ion is classified as either *x*, *y*, or *z*. A subscript indicates the number of residues in the fragment. In addition to the proton(s) carrying the charge, *c* ions and *y* ions abstract an additional proton from the precursor peptide. The structures of the six singly charged sequence ions are shown in Chart 4.4-2.

The above structures show only a single charge carrying proton. However, in electrospray ionization, tryptic peptides generally carry two or more charges, so fragment ions may carry more than one proton.

Internal Cleavage Ions. Double-backbone cleavage gives rise to internal fragments (Chart 4.4-3), which are usually formed by a combination of *b*-type and *y*-type cleavage to produce the illustrated structure, an amino-acylium ion. Sometimes, internal cleavage ions can form by a combination of *a*-type and *y*-type cleavage, an amino-immonium ion.

Immonium Ions. An internal fragment with a single side chain formed by a combination of *a*-type and *y*-type cleavage is called an immonium ion (Chart 4.4-4).

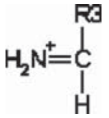

Chart 4.4-4.

Protein Identification with MS/MS Data. The previously described PMF uses the intact masses of the peptides to fit a protein in a sequence database. The MS/MS spectral matching employs the uninterpreted peaks in a peptide fragment spectrum to match to a theoretical fragment spectrum in a sequence database. This MS/MS spectrum is acquired from a collision-induced dissociation (CID) within a mass spectrometer. The fragmentations are produced either in a collision cell in a tandem mass spectrometer or within an ion trap. In an MS/MS-based protein ID experiment, multiple peptides are usually found and all of their fragment spectrums are used to identify the protein. In both PMF and MS/MS ID, the larger the number of peptides identified, the greater the confidence in the protein correlation. The correlation made with multiple MS/MS spectra are usually superior to the identification made in a PMF experiment. It is impossible to rely on a single peptide mass in a PMF experiment to correlate a protein. However, the heterogeneity imparted to a single peptide in an MS/MS experiment can generate enough amino acid sequence to correlate a protein. Tutorials from Ionsource website (http://www.ionsource.com/) for a step-by-step simplification of how sequence database search programs accomplish peptide and protein ID are provided in the following.

A Step-by-Step General Scheme for MS/MS Protein ID

Step 1. Enzyme specificity constraint: Some programs preindex the sequence database based on the enzyme specificity, which facilitates the search much faster because tryptic peptides can be indexed and mass lists can be premade. The downside is the necessity of a separate database to be indexed for each enzyme or each time a potential modification is changed.

Step 2. Peptide matching: It involves matching the parent mass of the intact peptide to the peptides in the database. Generally, the narrower parent mass constraint, the faster the search will proceed because fewer peptides will need to be correlated in the next step.

Step 3. Peptide listing and comparison: It takes the list of peptides identified by parent mass in step two and compares the theoretical fragment masses of these peptides to the experimentally derived fragment spectra.

Step 4. Peptide ranking: Hits are ranked by how many of the fragment masses match the theoretical fragment masses in the sequence database.

Step 5. Significance of hit: If more than one peptide is searched, all the peptides found are correlated to their prospective proteins. The protein with the greatest number of well-correlated peptides is usually the most significant hit.

Step 6. Probability factor and validation: Some programs show the probability number to back-up the proposed match, which gives the users some comfort in the designation. Select the most important individual protein hit and manually validate the spectral match.

In the following, we describe data management of PTM analysis of RIP140, where we detected 11 phosphorylation and eight acetylation sites.

4.4.7 MAPPING OF PTM SITES ON RIP140 BY LC–ESI–MS/MS ANALYSIS

Expression and Purification of RIP140 from Sf21 Insect Cells. Sf21 insect cells (1×10^6) were infected with recombinant Baculovirus vector. Using affinity chromatography under a denaturing condition, we were able to purify the recombinant protein to over 95% homogeneity [4]. The eluted protein from the affinity column was further resolved by a SDS–PAGE and a distinctly separated single band of RIP140 was obtained. The gel bands were excised for trypsin digestion and the tryptic peptides were analyzed by MALDI–TOF and LC–ESI–MS/MS.

SDS-PAGE, In-gel Tryptic Digestion of RIP 140. The purified His6-RIP140 protein (500 ng) from insect cells and GST-RIP140 (1 mg) from *E. coli* were resolved by an 8% SDS–PAGE. The bands were visualized by commassie staining. Gel slices containing RIP140 were subjected to overnight in-gel tryptic digestion The tryptic peptides were extracted from the gel with 5% acetic acid, followed by 5% acetic acid in 50% ACN. The digests and the extracted solution were combined and dried. The sample was re-dissolved in 5% acetic acid and desalted using ZipTip C18 reverse-phase desalting Eppendorf tips (Millipore). The peptides were eluted with 2% ACN containing 0.1% TFA to a volume of 50 μL.

Mass Spectrometric Analysis of RIP140. For identification of the proteins, the samples were analyzed by MALDI–TOF MS in a positive ion reflection mode (Qstar XL, Applied Biosystems) using α-cyano-4-hydroxycinnamic acid as a matrix. For LC-MS, the tryptic peptides were subjected to a 20-fold dilution using 2% acetonitrile in water containing 0.1% trifluoroacetic acid. An LC packings (LCP, a Dionex Company, Sunnyvale, CA) Famos autosampler aspirated 27.5 μL of the peptide solution into a 100-μL sample loop using the Famos μl-pick-up injection mode and 98:2 water:ACN, 0.1% formic acid (load buffer) as the transfer reagent. An LCP Switchos pump was used to concentrate and desalt the sample on an LCP C18 nano-precolumn (0.3 mm internal diameter × 5 mm length). The precolumn was switched in-line with a capillary column and peptides were eluted at 350 nL/min using an LCP Ultimate LC system. The capillary column (100 mm internal diameter) was packed in-house to 12 cm length with 5-μm, 200-Å pore size C18 particles. Peptides were eluted with a linear gradient of solvent B (5:95 water:ACN, 0.1% formic acid) from 0% (100% solvent A: 95:5, water:ACN, 0.1% formic acid) to 40% over 60 minutes and 40% to 90% for 5 minutes. The LC system was online with an Applied Biosystems, Inc. (ABI, Foster City, CA) QSTAR Pulsar quadrupole time-of-flight (TOF) mass spectrometer (MS), which was equipped with Protana's nano-electrospray source. An electrospray voltage of 2250 V was applied distal to the

analytical column. The TOF region acceleration voltage was 4 kV and the injection pulse repetition rate was 6.0 kHz. The $[M+3H]^{3+}$ monoisotopic peak at 586.9830 *m/z* and $[M+2H]^{2+}$ monoisotopic peak at 879.9705 *m/z* from human renin substrate tetradecapeptide (Sigma-Alrdich, St. Louis, MO) were used for external calibration. As peptides eluted from the column, they were focused into the MS. The IDA was used to acquire MS/MS data with experiments designed such that the three most abundant peptides were subjected to collision-induced dissociation, using argon as the collision gas every 15 seconds. Collision energies were varied as a function of the *m/z* and the charge state of each peptide. To avoid continued MS/MS of peptides that had already undergone collision-induced dissociation, a dynamic exclusion was incorporated for a further 45 seconds. IDA mode settings included continuous cycles of three full-scan TOF MS of 400–550 *m/z*, 550–750 *m/z*, and 750–1200 *m/z* (1.5 seconds) plus three product ion scans of 50–4000 *m/z* (3 seconds each). Precursor *m/z* values were selected from a peak list automatically generated by Analyst QS software (ABI) from the TOF MS scans during acquisition, starting with the most intense ion. Peptide mass software MS–Digest from the ProteinProspector (available online http://prospector.ucsf.edu) was used to generate a theoretical tryptic digest of RIP140 by considering serine-, threonine-, and tyrosine-containing peptides to account for phosphorylation and lysine for acetylation. From the LCMS data, the molecular weights of the detected peptides were calculated using the LCMS reconstruct feature of Analyst QS. Experimentally measured peptide masses were compared with the theoretical digest. To confirm the sequence of the peptides and the sites of modification, MS/MS spectra were examined. Peaks with a minimum height of 3% relative to the base peak were considered and a 100-ppm tolerance was used to establish matches with the theoretical b and y ions that were predicted using Bioanalyst software (Applied Biosystems). In addition, in all cases, the data from IDA experiments were searched using MASCOT (http://www.matrixscience.com) MS/MS data search.

Mapping of Phosphorylation and Acetylation Sites on RIP140. The tryptic digested samples were first analyzed by MALDI–TOF mass to identify the RIP140 and posttranslational modification by phosphorylation at serine, threonine, and tyrosine residues and acetylation sites on lysine residues. The MALDI–TOF MS data were subjected to a MASCOT search at the NCBI data bank. The mass tolerance of both precursor ions was set at 175 ppm, carbamidomethyl cystein was specified as a static modification, and phosphorylated serine, threonine, and tyrosine and acetylation on lysine residues were specified as variable modifications. The search result confirmed the identification of the protein with significant sequence coverage to over 60% of the total protein [4]. However, only a few phosphopeptides were predicted from the MALDI–TOF mass data. The MS/MS analysis was carried out for the precursor ions of the predicted phosphopeptides and acetylated peptides to identify the peptide sequence and phosphorylation/acetylation sites. Unfortunately, in most cases, high-quality MS/MS spectra for the identification of the phosphorylation sites by MALDI–TOF mass were not obtained. However, sequences of the unmodified peptides were identified properly from the MS/MS analysis. Based on this information, we speculated that the poor quality of MS/MS spectra of the phosphopeptides/acetylated peptides could be caused by improper ionization of the RIP140 tryptic peptides by MALDI. Therefore, LC–ESI–MS/MS was applied

using nanoelectrospray source for ionization to solve this problem. We recorded three independent full-scan ion chromatograms of 400–550 *m/z*, 550–750 *m/z*, and 750–1200 *m/z*. The IDA was used to acquire MS/MS data. IDA analyses were performed on the tryptic digests of RIP140 expressed in *E. coli* and insect cells. The data from IDA experiments were searched using a MASCOT search. The mass tolerance of both precursor ion and the MS/MS fragment ions was set at ±0.1 Da and carbamidomethyl cystein was specified as a static modification. Phosphorylated serine, threonine, and tyrosine and acetyaled lysine were specified as variable modifications. The result revealed 11 tryptic phosphopeptides (Table 4.4-1) and eight acetylated peptides (Table 4.4-2) from RIP140 expressed in insect cells. For a control, no phosphorylated/acetylated peptides were detected from RIP140 expressed in *E. coli* [4, 5, 34].

Mapping of Phosphorylation Sites. The MS/MS data of the phosphopeptides in comparison with the unmodified form were analyzed manually to map the phosphorylation sites on RIP 140. As an example, the MS/MS spectrum of tryptic peptide spanning residues (100–111) is presented to explain how phosphorylation was assigned (Figure 4.4-2). The MS/MS fragmentation patterns for both the precursor ions of the unmodified (top panel) and modified peptide (bottom panel) residues 100–111 were identical, especially from *b*1 to *b*4 ions and *y*1 to *y*4 ions. The *b*5 ion of the unmodified form appeared as a singly charged ion at 559.26 *m/z*, whereas the *b*5 ion in the phosphopeptide appeared at 541.26 *m/z* because of a −18 amu delta-mass shift. This delta-mass shift was considered to be the β-eliminated product of *b*5 ion caused by loss of either H_3PO_4 or H_2O from Ser-104. Similar β-elimination was also shown at *b*6 ion of the modified peptide. The *b*8 ion of the modified peptide showed an 80-amu (H_3PO_4) delta-mass shift (965.39 *m/z*) along with its β-eliminated ion signal at 867.41 *m/z* due to loss of H_3PO_4 (98 amu). These data asserted that the β-eliminated *b*5 and *b*6 ions were from the loss of H_3PO_4 from Ser-104. Thus, the phosphorylation site was assigned to Ser-104. This phosphorylation site was also confirmed by an independent MS/MS analysis (data not shown) of the phosphopeptide residues 101–111 and 101–112 (Table 4.4-1).

Mapping of Acetylation Sites on RIP140. The MS/MS data of the acetylated peptides were also analyzed manually to identify the acetylation sites on RIP140. To identify the acetylated peptides, a 42-amu mass shift was considered as an indication of acetylation. To distinguish acetylation from trimethylation, both rendering the same integral mass shift, some marker ion signals, such as an immonium ion at 126 *m/z* specific for acetylated lysine was monitored [35, 36]. In addition, the absence of a marker ion for trimethylated lysine generated from loss of trimethylamine from b or y ions as $[M-59]^+$ was also confirmed. Significant differences in mass shift were caused by loss of acetyl moiety (42 *m/z*) and trimethylamine (59 *m/z*). Therefore, a 42-amu net loss for acetyl group from y or b ions was also accounted to assign the acetylation sites [33, 34]. Initial analysis of the mass data showed some peptides displaying a 43-unit mass shift instead of 42 units for acetylation, which raised a possibility of carbamylation of lysine residue rather than acetylation in the modified peptides. But careful analysis of MS/MS data finally confirmed that this 1-unit positive delta mass shift was originated from the deamidation of either glutamine or asparagine residue present in the acetylated peptides. All of these

TABLE 4.4-2. LC–ESI–MS Profile of the ACTEYLATED Tryptic Peptides of RIP140 [5]

Tryptic digests of RIP140 protein was subjected to LC–ESI–MS/MS. Three independent full-scan ion chromatograms from *m/z* 400–550, 550–750, and 750–1200 were recorded in an information-dependent acquisition (IDA) mode to acquire MS/MS data. The IDA data were searched online at MASCOT (http://www.matrixscience.com) MS/MS data search at the NCBI data bank. The MS/MS data were analyzed manually to confirm the sequence of the modified and the unmodified forms of the same peptide identified by the data bank search. The full scan chromatograms were analyzed to assign the charged state, retention time, and intensities of the peptides.

[1] The 43-unit mass difference between modified and unmodified peptides appeared because of acetylation of lysine along with deamidation of either asparagine (N) or glutamine (Q) residues present in the peptides.

[2] RT, retention time in minutes.

[3] M^+, precursor ion.

parameters were evaluated carefully while MS/MS data were analyzed to sequence the modified peptides. In addition, the MS/MS spectra of the modified peptide were always compared with the unmodified peptide (data not shown) for fingerprinting purposes.

We provide an example of how an acetylation site can be identified by manual analysis of MS/MS spectrum. The acetylated peptide-spanning residues 101–112 displayed a doubly charged ion at 686.88 *m/z* (precursor 1371.75 *m/z*) in total ion chromatogram (TIC). The precursor ion showed a 43-unit mass shift caused by acetylation of a lysine and deamidation from an asparagine residue. The MS/MS spectrum of the modified peptide showed *y*1 ion at 147.1 *m/z* and *y*1° ion at 129.1 *m/z* caused by loss of H_2O, which were identical to the unmodified peptide (Figure 4.4-3). The *y*2 ion appeared at 317.2 *m/z* instead of 275.2 *m/z*, resulting in

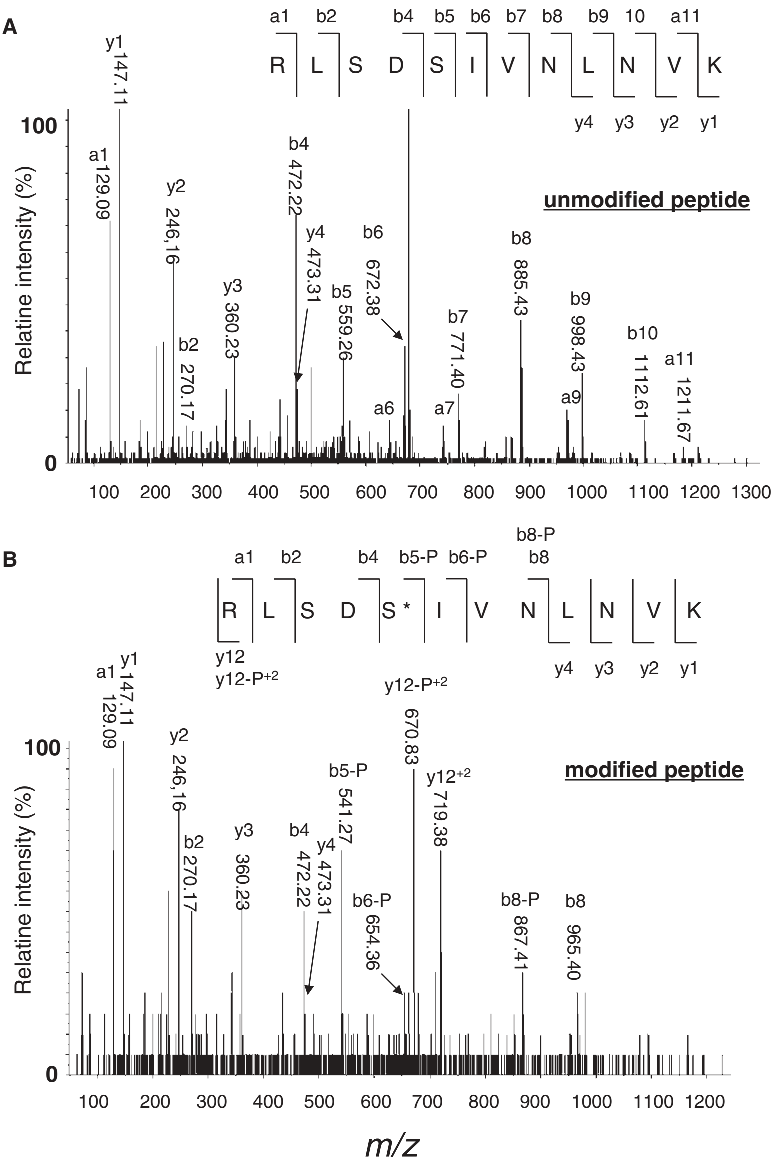

Figure 4.4-2. CID–MS/MS spectra peptide residues 100–111 form RIP140. Both spectra (unmodified, top and phosphorylated, bottom) showed identical b4 ions at *m/z* 472.22, but the b8 and b5 ions of the phosphopeptide showed 80 and −98 units mass shift, respectively, suggesting Ser-104 phosphorylation. (Courtesy: *Proteomics*, 5:2157–2166.)

a net mass shift of 42 Da, which confirmed the modification of Lys-111 by acetylation. The presence of a marker ion at 126 *m/z* specific for lysine acetylation confirmed this modification originated from acetylation rather than trimethylation [35, 36], which was further substantiated by the presence of consecutive *y* ions from *y*2 to *y*8 due to modified lysine residue. The *y* ions starting from *y*4 showed a 43-amu shift instead of 42, suggesting deamidation of Asn-109.

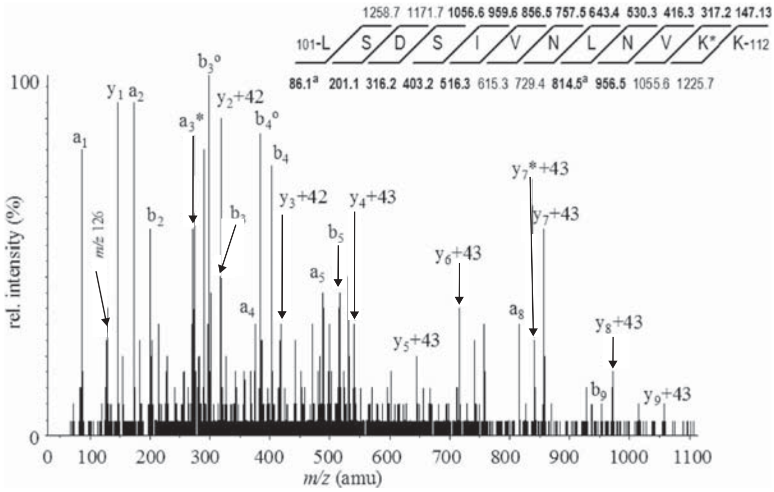

Figure 4.4-3. CID–MS/MS spectra of acetylated peptides spanning residues 101–112 from RIP140. The y1 ion at *m/z* 147.1 was identical to the native peptide, but the y2 and y3 ions showed a 42-unit mass shift, suggesting Lys-111 acetylation. (Courtesy: *Molecular & Cellular Proteomics,* 4:975–983.)

4.4.8 THE ROLE OF PTM IN CELLULAR FUNCTION AND CELL SIGNALING

Phosphorylation. Phosphorlation is the most well-studied PTM, and it occurs on a large number of proteins. We examined PTM of RIP140, which primarily functions as a lignad-dependent co-repressor for many nuclear receptors by recruiting HDACs in the transcription complex [34]. RIP140-null mice exhibited reproductive defects as well as abnormal energy homeostasis. We identified 11 phosphorylated sites including Ser^{104}, Thr^{202}, Thr^{207}, Ser^{358}, Ser^{380}, Ser^{488}, Ser^{519}, Ser^{531}, Ser^{543}, Ser^{672}, and Ser^{1003} [4, 34]. The MAP kinase-mediated phosphorylation of Thr^{202}, Thr^{207}, and Ser^{358} enhances the repressive potential of RIP140 by facilitating the recruitment of HDAC3. We generated constitutive dephosphorylated mutant by replacing the phosphorylated Ser/Thr with Ala and a constitutive positive mutant by replacing phospho-Ser/Thr with glutamic acid. The Ala-null mutant was unable to exert the repressive activity, whereas the constitutive positive mutant became more repressive [34], which demonstrates that phosphorylation of RIP140 critically modulates its biological activity.

In another study, we asked whether and how the orphan nuclear receptor 2 (TR2) can activate its target genes by phosphorylation without ligands [18]. We hypothesized that PTM of TR2 can modulate TR2 function without a putative ligand. We showed that, indeed, PKC-mediated phosphorylation of TR2 enhanced its stability and activation potential for its target RARβ2. We identified PKC-mediated phosphorylation on the ligand-binding domain of TR2 at Ser-461 and Ser-568, which enhanced its protein stability. We further identified phosphorylation of the DNA-binding domain (DBD) of TR2 at Ser-170 and Ser-185, which facilitated its DNA-binding ability and recruitment of coactivator p300/CBP-associated factor (P/CAF) [39]. Ser-185 is required for DNA binding, whereas both Ser-170

and Ser-185 are necessary for receptor interaction with P/CAF [18]. For a comprehensive review of phosphorylation of nuclear receptors, see the review by Rochette-Egly [14].

Acetylation. Acetylation is another widely known PTM. Many nuclear receptors (NRs) and transcription factors are known be modified by acetylation. We have also shown that RIP140 can be acetylated on eight lysine residues, including Lys^{111}, Lys^{158}, Lys^{287}, Lys^{311}, Lys^{482}, Lys^{529}, Lys^{607}, and Lys^{932}. The amino-terminal region [amino acids (aa) 1–495] was more repressive and accumulated more in the nuclei under a hyperacetylated condition, whereas hyperacetylation reduced the repressive activity and nuclear translocation of the central region (aa 336–1006). Hyperacetylation also enhanced the repressive activity of the full-length protein and triggered its export into the cytosol. This study revealed differential effects of PTM on various domains of RIP140. Recent reviews described nuclear receptors and transcription factors that can be modified by acetylation [22, 40].

Tyrosine Nitration. Tyrosine nitration is one of the protein modifications induced by reactive oxygen species. NO is an important factor that induces posttranslational modifications of proteins by cellular reduction and oxidation mechanism: cysteinyl-nitrosylation or Tyr nitration. Nuclear factor (NF)-kappaB activity can be rapidly suppressed by sodium nitroprusside, an NO donor. This effect was effectively reversed by peroxynitrite scavenger deferoxamine, suggesting a Tyr nitration-mediated mechanism. Tyr nitration of p65 induced its dissociation from p50, its association with IκBα, and subsequent sequestration of p65 in the cytoplasm by IkBa-mediated export. LCMS revealed specific nitration on Tyr-66 and Tyr-152 residues of p65, which were confirmed by mutation studies. These residues are important for the direct effects of NO on p65, which resulted in more p65 export and inactivation of NF-κB activity. This study identified a novel and efficient means in which NO rapidly inactivated NF-κB activity by inducing Tyr nitration on p65 [12].

4.4.9 PROTEIN POSTTRANSLATIONAL MODIFICATION AND DISEASES

The establishment of species- and tissue-specific protein databases provides a foundation for proteomics studies of diseases. Continual development will lead to functional proteomics studies, in which identification of protein modification in conjunction with functional data from established biochemical and physiological methods enables the examination of interplay between changes in a proteome and the progression of diseases. Recently, many investigations provided direct evidence for PTM in the pathophysiological progression of many diseases like diabetes, Alzheimer's diseases (AD), atherosclerosis, and oncogenesis.

Cardiovascular Diseases. In a comprehensive cardiovascular proteome analysis, various PTMs were documented in dilated cardiomyopathy [41]. A 2-DE analysis of dilated cardiomyopathy-diseased human myocardial tissue revealed more than 50 HSP27 proteins by iummunoblotting, illustrating a large number of PTMs potentially occur on a single protein [42].

Neurodegenerative Diseases. Mircotubule-associasted protein *tau* is documented to undergo several PTMs and aggregates into paired helical filaments (PHF) in AD and other taupathies [43]. PTMs of *tau* include hyperphosphorylation, glycosylation, ubiquitination, glycation, polyamination, nitration, and proteolysis. Hyperphosphorylation and glycosylation are crucial to the molecular pathogenesis of neurofibrillary degeneration of AD [43]. The others appeared to represent a failed mechanism for neurons to remove damaged, misfolded, and aggregated proteins. Therefore, it was proposed that modified *tau* can serve as a biomarker for the diagnosis of AD.

Diabetes. Very recent investigation showed methylglyoxal modification of mSIN3 protein and its linkage to diabetes retinopathy [44]. The report showed that in diabetes, because of impaired metabolism of glucose, the level of glyoxal concentration increased. This glyoxal can modify proteins and finally can modulate gene transcription.

Aging and Age-related Diseases. Oxidatively modified proteins increase as a function of age. Studies revealed an age-related increase in the level of protein carbonyl content, oxidized methionine, protein hydrophobicity, and cross-linked and glycated proteins [9]. Factors reducing protein oxidation increase the life span of experimental animals and vice versa. Furthermore, a number of age-related diseases are shown to associate with an elevated level of oxidized proteins. The accumulation of oxidatively modified protein can be attributed to a multitude factors that govern (1) the rate of formation of various kinds of reactive oxygen species, (2) the level of antioxidant defense that guards proteins against oxidative modification of proteins, (3) the sensitivity of proteins to oxidative attack, and (4) the repair and elimination of damaged proteins. The ROS are formed by ionizing radiation, activation of neutrophils and macrophages, oxidase catalyzed reaction, lipid peroxidation, and glycation/glycoxidation reactions. It is well established that the accumulation of oxidized protein is associated with a number of diseases. Elevated levels of protein carbonyls have been found in AD diseases, amyotrophic lateral scelerosis, cataractogenesis, systemic amyloidosis, muscular dystrophy, Parkinson's disease, progeria, Warner's syndrome, rheumatoid arthritis, and respiratory distress syndrome. Elevated levels of proteins modified by lipid peroxidation products are associated with Parkinson's diseases, cardiovascular diseases, iron-induced renal carcinogenesis, and experimental pancreatitis and atherosclerosis. Elevated levels of protein glycation/glycoxidation endproducts (AGEs) are associated with diabetes mellitus, ADs, atherosclerosis, Parkinson's diseases, and Down's syndrome. Elevated levels of protein nitrotyrosine damaged are associated with atherosclerosis, AD, lung injury, multiple sclerosis, and endotoxemia.

Cataractogenesis. Cataractogenesis has been noted in the human lens, due to PTM of lens protein αβ-crystallin by carbamylation and acetylation at Lys-92 [45].

Autoimmune Diseases. PTM can dictate an antigen in eliciting autoimmune diseases. For example, isoaspartyl posttranslational modification (conversion of aspartic acid to isoaspartic acid) has been shown to trigger autoimmune response to self-proteins. The presence of isoaspartyl proteins has been observed as a major component of the amyloid containing brain plaques of patients with AD [46].

Alcoholism. Many investigations showed that alcoholism modulates the level of PTM-like phosphorylation [47]. Alcohol consumption was shown to decrease the sialic acid conjugation to transferrin, an important carrier protein secreted from the liver to blood and other glycoproteins. This observation led to the development of a laboratory test for chronic alcohol use. Similar studies showed that direct production of alcohol metabolism (alpha-hydroxyethyl radicals, acetaldehyde and lipid peroxides) causes PTM that correlates with alcohol consumption in animal models and human subjects [48].

4.4.10 PTM AS A TARGET FOR THERAPEUTIC DEVELOPMENT

Histone deacetylase (HDAC) inhibitors are the new class of agents that modulate gene expression by altering chromatin structure and gene transcription. Several classes of HDAC inhibitors are known as therapeutics for tumors. The depsipeptides (FR901228 or FK228) are under clinical trial [49]. Three other classes including short-chain fatty acids (phenylbutyrate and valproic acid), benzamides (Cl-994 and MS-27-275), and hydroxamic acid (suberoylanilide hydroxamic acid) are being developed. An attractive model is that the increase in histone acetylation leads to transcriptional activation of a few genes that can inhibit tumor growth. Ten structurally related HDACs have been described and fall into two classes [50, 51]. Class I HDACs consist of HDAC1, 2, 3, and 8; whereas class II HDACs consist of HDAC4, 5, 6, 7, 9, and 10. Members of a third class of HDACs (class III) are structurally unrelated to the human class I and class II HDACs, and they consist of homologues of the yeast Sir2 proteins [52]. The activity of class I and class II HDACs is inhibited by short-chain fatty acids and hydroxamic acids, but class III HDACs are not inhibited by these agents. Therefore, one major challenge is to identify specific HDACs inhibitors.

Another report showed curcumin (a component of many tropical spices) as a novel histone acetyl transferase (HAT) inhibitor [53]. The report showed that curcumin could block acetylation of histone and p53 *in vivo*, which led to apoptosis of Hela cells. Therefore, potential in the future exists to develop HAT inhibitors for managing cancers.

Similarly, histone arginine/lysine methylation can be the target for the development of therapeutics. The status of histone arginine methylation is intimately involved in gene transcription. Recently, several compounds were found to inhibit protein arginine methyltransferases (PRMTs) [54]. It can also be interesting to explore how this small molecule could be exploited for developing therapeutics.

Protein farnesylation is a lipid-conjugate-type posttranslational modification required for the cancer-causing activity of the GTPase Ras [55]. Although farnesyltransferase inhibitors (FTIs) are in clinical trials, their mechanism of action and the role of protein farnesylation in normal physiology are poorly understood. Protein farnesylation was found to be essential for early embryogenesis, dispensable for adult homeostasis, and critical for progression, but not initiation, of tumorigenesis. Preclinical work has revealed FTIs' ability to effectively inhibit tumor growth in vitro and in animal models across a wide range of malignant phenotypes. Acute myeloid leukemias (AMLs) are appropriate disease targets in that they express relevant biologic targets such as Ras, MEK, AKT, and others that may

depend on farnesyl protein transferase activity to promote cell proliferation and survival. Phase I trials in AML and myelodysplasia have demonstrated biologic and clinical activities as determined by target enzyme inhibition, low toxicity, and both complete and partial responses. As a result, phase II trials have been initiated to further validate the clinical efficacy and to identify downstream signal transduction targets that may be modified by these agents [56].

We have recently reported rapid inactivation of NF-kappa B by tyrosine nitration [12]. As NF-kappaB is involved in many cellular functions in response to inflammatory responses [57], it can be a very important target in antioxidation therapy.

Nuclear receptors (NRs) orchestrate the transcription of specific gene networks in response to binding of their cognate ligands. They also act as mediators in a variety of signaling pathways by integrating diverse PTMs. NR phosphorylation concerns exist on all three major domains. Often, phosphorylation of NRs by kinases that are associated with general transcription factors (e.g., cdk7 within TFIIH) or activated in response to a variety of signals (MAPKs, Akt, PKA, PKC) facilitates the recruitment of coactivators and, therefore, cooperates with the ligand to enhance transcription activation. But phosphorylation can also contribute to the termination of the ligand response through inducing DNA dissociation, triggering NR degradation or decreasing ligand affinity. These different modes of regulation reveal an unexpected complexity of the dynamics of NR-mediated transcription. Therefore, small molecules that can modulate the phosphorylation status of NR can also be developed as therapeutics [14, 19]. For comprehensive reviews on PTM as targets in therapeutic development, the readers are referred to review Refs. 57–59.

FURTHER READING

Proteomic Resources

The readers are referred to the following websites, journals, and suppliers to acquire comprehensive knowledge about the proteomics resources.

World Wide Web (WWW) Resources (short listed)

http://www.matrixscience.com/: Theoretical digestion, database search option (intact protein) for PMF by MALDI–TOF MS data, LC–ESI–MS/MS data search for PMF and PTM identification. Other information, like MS/MS fragmentation and PTM, is also available.

http://proteinprospector.uscf.edu: Theoretical digestion using MS-Digest. One of the unique options in using MS–Digest is that one can generate theoretical MS of the modified peptide selecting a wide variety of PTMs. Database search for PMF can be done using MS-Fit and also mass peak list information from the common contaminants, for example, keratin and trypsin autolysis peaks in MS are available.

http://ca.expasy.org/: Protein database, calculation of protein MS and pI values, theoretical digestion. Prediction of varieties of PTMs (glucosylation, phosphorylation, sumoylation, etc.) can be done from the protein sequence.

http://www.ionsource.com/: Very helpful tutorials about PMF using MALDI–TOF MS and ESI–MS/MS, *de novo* protein sequencing and related information. This website provides

very helpful tips and information for beginners in proteomics. One can also get many other website links for proteomics resources from this website.

Literature and Journals:

(1) Proteomics, (2) Journal of Proteome Research, (3) Molecular & Cellular Proteomics, (4) Electrophoresis, and (5) BBA protein-proteomics.

Vendors and Suppliers:

A comprehensive lists of vendors and suppliers related to proteomics resources are available on Ionsoure website (http://www.ionsource.com/).

4.4.11 CONCLUSION

The understanding of PTM will advance as more new PTMs are explored as biomarkers and more powerful techniques and tools are developed. It can be predicted that, within a few years, PTM analysis can become a routine procedure like HPLC in chemistry or PCR in biology laboratories. Currently, research of PTM is focusing on the basic principle and the studies of biological problems. Predictably, it will gradually be applied to the discovery of molecular targets for disease intervention and the development of therapeutics.

4.5.1 INTRODUCTION

Poly(ethylene glycol) (PEG) is a synthetic neutral polymer that is soluble in water as well as in many organic solvents, such as methylene chloride, ethanol, acetone, and chloroform. In aqueous solutions, PEG is highly hydrated due to the presence of the ether oxygen linkage as a hydrogen bond acceptor. The hydrated PEG has a high degree of segmental flexibility and large excluded volume. These properties enable PEG to behave as if 5–10 times larger than proteins of comparable molecular weights and to effectively exclude other polymers (both natural and synthetic) from PEG-grafted surfaces [1, 2]. As PEG is demonstrated to be nontoxic, the U.S. Food and Drug Administration (FDA) has approved it for use as a vehicle or base in foods, cosmetics, and pharmaceuticals, including injectable, topical, rectal, and nasal formulations. When injected into the bloodstream, PEG is rapidly removed from the body with clearance rates inversely proportional to polymer molecular weights [3]. PEG tends to accumulate in muscle, skin, bone, and liver to a higher extent than other organs irrespective of the molecular weights, and its elimination occurs either in the kidneys (for PEGs $< 30\,\text{kDa}$) or in the feces (for PEGs $> 20\,\text{kDa}$) [3, 4]. There have been no reports on the generation of antibodies to PEG under routine clinical administration of PEG–protein conjugates. A few reports have indicated production of antibodies to PEG under extreme experimental conditions using animals [5, 6]. It is important to note, however, that the minute quantities of PEG in therapeutic conjugates are generally considered to provide no chance of eliciting unwanted host responses.

PEGylation is the process of attaching PEG to various objects, such as peptides, proteins, cells, and other biologically active materials. As PEG has a unique set of properties in a biological environment, PEGylation of the target molecules has provided a wide range of biomedical applications. It has been demonstrated that PEGylated proteins have less toxicity [7, 8] and less immunogenicity [9, 10]. Increase in the molecular weights of proteins by PEGylation slows down kidney ultrafiltration, resulting in prolonged circulation in the bloodstream. The shielding effect of PEG reduces protein degradation by the enzymatic reaction and minimizes recognition of the immune system. In addition to proteins, recent efforts have made significant progress in designing PEGylated cells that show low immunogenic recognition, thus allowing transplantation. PEGylation has also been used to modify surfaces of drug and gene carriers to improve the blood circulation time and targeting efficiency.

4.5.2 PEGYLATED PROTEINS

4.5.2.1 Chemical Modification

Although therapeutic proteins are highly potent endogenous substances, they are generally susceptible to proteolytic degradation, aggregation, polymerization, and adsorption onto foreign surfaces. In addition, most proteins have short biological half-lives and often induce immunogenic responses when administrated into the body. In an attempt to stabilize proteins toward proteolysis and to increase blood circulation time in the body, various water-soluble polymers, such as polysaccharides [11, 12] and albumin [13], have been used for protein conjugation. Of the numerous natural and synthetic polymers, PEG is becoming a standard polymer

for chemical modification of proteins and peptides to enhance their pharmaceutical properties. The pioneering first steps in PEGylation of proteins were taken in the late 1970s by Professor Frank Davis and his colleagues at Rutgers University [4].

PEG is a linear or branched polyether terminated with hydroxyl groups that is synthesized by anionic ring opening polymerization of ethylene oxide. The molecular weights of linear PEGs available for biomedical applications usually range between a few hundred to several tens of thousands of daltons. For PEGylation of proteins, the reactive functional groups at the chain end of PEG need to be introduced. The functional group is selected based on the type of available reactive groups on proteins, originating from lysine, cysteine, histidine, arginine, aspartic acid, glutamic acid, serine, threonine, tyrosine, N-terminal amino group, and C-terminal carboxylic acid.

PEGs for Carboxyl Conjugation. The nucleophilic PEG derivatives, such as PEG-amine and PEG-*p*-aminobenzylether [14], have been attached by the reaction with carbodiimide-activated carboxylic groups of proteins. For PEG-amine, this approach has been limited because the reactivity of PEG-amine is similar to that of the amino groups of proteins, resulting in poor selectivity. On the other hand, PEG-*p*-aminobenzylether is useful for selective reaction at a slightly acidic solution (pH 4.8–6.0) because it has the lower pKa value than the primary amino groups of the protein. Also, PEG-hydrazide (pKa ~ 3) can specifically react with the carbodiimide-activated carboxyl groups of proteins under acidic conditions (pH 4.5–5) at which primary amino groups of proteins are unreactive due to the protonation. It should be considered for protein modification, however, that the nucleophilic PEG derivatives often involve side reactions, including modification of tyrosyl and cysteinyl side groups and formation of *N*-acylurea derivatives [15, 16].

PEGs for Amine Conjugation. The most common reactive sites on proteins for PEGylation are the alpha or epsilon groups of lysine or the *N*-terminal amino groups of other amino acids [17]. To react with amino groups of proteins, PEG has been activated by a variety of chemical modifications. Figure 4.5-1 shows various chemical structures of activated PEGs.

Activated PEGs can be prepared by reacting the primary alcohol group of PEG with the chlorine group of trichloro-s-triazine (cyanuric chloride), by which two remaining chlorine groups are available for protein modification [18]. The resulting PEG-dichlorotriazine (Figure 4.5-1a) can react with nucleophilic functional groups on the surface of proteins such as lysine, serine, tyrosine, cysteine, and histidine [19]. One chloride is displaced during the reaction, whereas the other remains less reactive and may provide the possibility of the side reaction causing chemical cross-linking of protein molecules. PEG-tresylates (Figure 4.5-1b) were used to nonspecifically modify amino groups to form secondary amine linkages that are stable and does not change the total charge of the conjugate, compared with the native protein [20]. PEG-tresylates have more specific reactivity to amino groups than PEG-dichlorotriazine, whereas they may involve the side reactions such as formation of a degradable sulfamate linkage [21].

PEG-aldehydes (Figure 4.5-1c) are a useful electrophilic reagent capable of specifically reacting with amino groups of proteins without interference from other nucleophiles belonging to proteins [22]. The reaction of PEG-aldehyde with protein proceeds through a reversible Schiff base intermediate that is reduced in the

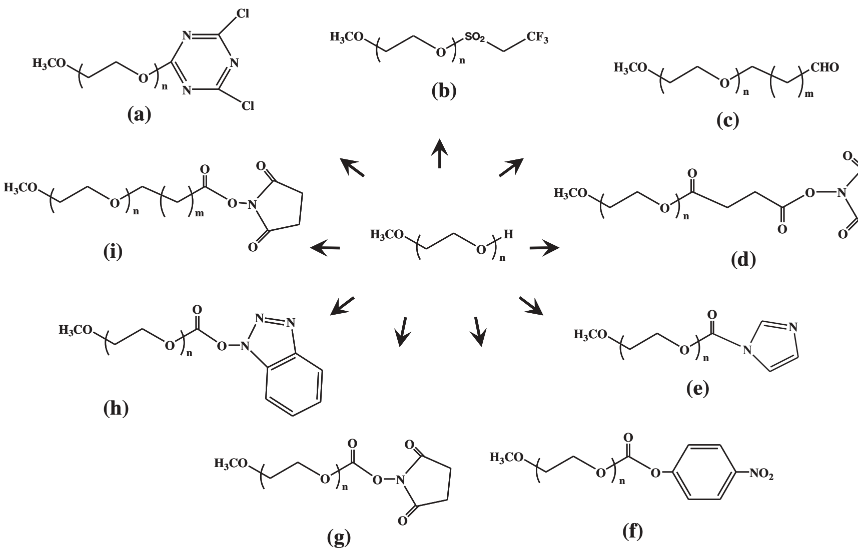

Figure 4.5-1. Chemical structures of activated PEGs for amine conjugation: (a) PEG-dichlorotriazine; (b) PEG-tresylate; (c) PEG-aldehydes; (d) PEG-succinimidyl succinate; (e) PEG-imidazole carbonate; (f) PEG-phenyl carbonate; (g) PEG-succinimidyl carbonate; (h) PEG-benzotriazole carbonate; and (i) PEG-active ester.

presence of sodium cyanoborohydride or sodium borohydride. Also, PEG-aldehyde has the ability to achieve selective modification between N-terminal α-amines and lysine ε-amines. When the reaction is performed under mild acidic conditions (pH 5–6), the α-amino groups are preferentially reacted with PEG-aldehyde. PEG-succinimidyl succinate (Figure 4.5-1d) is prepared by reaction of PEG with succinic anhydride, followed by carbodiimide-mediated condensation with N-hydroxy succinimide (NHS) [23]. This activated PEG reacts with proteins under mild conditions (pH < 7.8, room temperature), and the conjugates show comparable biological activities with native proteins [23, 24]. As the conjugates contain the ester linkage between PEG and protein, exposure to the physiological condition may induce hydrolysis, leading to loss of the benefits of PEG grafting. Katre et al. [25] demonstrated that the hydrolysis rate can be slowed by substituting the succinate group with a glutarate. PEG-imidazole carbonates (Figure 4.5-1e) and PEG-phenyl carbonates (Figure 4.5-1f) are prepared by reacting carbonylimidazole [17, 26] or chloroformate [27] with the terminal hydroxyl group of PEG, respectively. These derivatives have been used to produce conjugates via the formation of a carbamate bond between PEG and proteins. In general, they show much lower reactivity than PEG-succinimidyl succinate. The reaction time takes more than 24h. The slower reaction rate is beneficial for selective modification of amino groups in proteins, thus producing conjugates with preserved biological activity.

PEG-succinimidyl carbonate (Figure 4.5-1g) is another activated PEG that specifically reacts with amino groups of proteins, thus forming a carbamate linkage [28]. It is found to be more selective than PEG-succinimidyl succinate for modification of the amino groups of proteins. In particular, PEG-succinimidyl carbonate is

highly useful to prepare a minimally toxic conjugate because the liberated NHS produced by the reaction is known to be nontoxic. PEG-benzotriazole carbonate (Figure 4.5-1h) is similar to PEG-succinimidyl carbonate. PEG-benzotriazole carbonate forms the carbonate bonds via modification of proteins and is more selective than PEG-succinimidyl succinate in reacting with amino groups of proteins [29]. Furthermore, PEG-benzotriazole carbonate can react under mild conditions within a short reaction time (e.g., pH 8.5 at 25°C for 30 min). Despite their high selectivity, both PEG-succinimidyl carbonate and PEG-benzotriazole carbonate have been recently reported to react with histidine and tyrosine residues of proteins, which forms hydrolytically unstable linkages such as imidazolecarbamate [30].

In recent years, the most popular PEG derivatives for protein modification have been active esters of PEG carboxylic acids (Figure 4.5-1i) [17]. As the active esters react with primary amines to form the amide linkage under physiological conditions, they are useful for preparing stable conjugates. PEG carboxylic acids are readily activated by reacting them with NHS and carbodiimide. Of various PEG-active esters, the succinimidyl ester of carboxymethylated PEG was the first derivative developed for protein modification [31]. This derivative, however, is extremely reactive toward hydrolysis that limits the extended applications. The reactivity of PEG-active esters was found to be controlled by changing the distance between the active ester and the PEG backbone [32]. For example, the hydrolysis half-life of carboxymethylated PEG is 0.75 min at pH 8 and 25°C, whereas those of PEG-active esters bearing one and two additional methylene groups between PEG and active esters are 16.5 and 23 min, respectively, under the same condition.

PEGs for Cysteine Conjugation. Several PEG derivatives have been developed to specifically react with the thiol group of cysteines, including PEG-maleimide [33], PEG-orthopyridyl-disulfide [34], PEG-iodoacetamide [33], and PEG-vinyl sulfone [35]. These cysteine-targeting PEG derivatives are primarily designed for site-specific PEGylation of proteins because cysteine residues are rarely found on the surface of proteins, compared with lysine residues. If necessary, however, it is possible to add cysteine residues on the protein surfaces by genetic engineering, which may allow site-specific modification at areas that do not affect the biological activity of protein. Each derivative has its own characteristics. For example, the reaction of PEG-maleimide with the free thiol group is known to form a hydrolytically stable thioether linkage throughout the Michael-addition reaction. PEG-orthopyridyl-disulfide can react with protein sulfhydryl groups to form a disulfide bond capable of being cleaved to regenerate the native protein under reducing conditions. PEG-iodoacetamide reacts slowly with protein thiols by nucleophilic substitution via formation of a stable thioether linkage. For this polymer, the reaction should be carried out in a dark condition to prevent the generation of free iodine that may react with other amino acids such as tyrosine. PEG-vinyl sulfone is another activated PEG reacting with protein thiols to form a stable thioether bond.

PEGs for Selective Modification. In an attempt to produce PEGylated proteins with preserved biological activity, selective modifications are often required. In most cases, the successful protein modification depends on the balance between reactivity and selectivity. It is generally accepted that the selective modification is

achieved by using less-reactive PEG derivatives, in which the reaction is performed at the low temperature for the long time period (>24 h).

Based on the reversible protection of interfering nucleophilic groups, selected amino groups in proteins have been modified with PEG. The protected intermediates of proteins are first prepared by chemically attaching the protective reagent to the amino groups that play an important role in biological activity. PEG is then conjugated to the preferred sites on the surfaces of proteins. The subsequent deprotection of PEGylated intermediates affords the final products that may show comparable activities with native proteins. This approach allowed selective modifications with PEG for insulin [36, 37], vapreotide [38], and tumor necrosis factor-alpha (TNF-α) [39].

The site-specific modifications of proteins with PEG have also been achieved by the enzyme-mediated coupling reaction [40]. One representative enzyme for this approach is a genetically engineered glutamine aminotransferase that can be used to selectively conjugate PEG to glutamine residues in a recognized substrate sequence. Interleukin-2, site-specifically PEGylated by this method, showed good *in vitro* activities and increased half-lives, compared with the native protein [40].

Thiol-specific PEG derivatives are useful for selective modification of proteins because a few cysteine sulfhydryl groups are generally available on the surface of proteins. The addition of cysteine residues at specific sites in a protein sequence is possible by genetic engineering, allowing site-specific PEGylation of proteins. Chapman et al. [41] have developed PEGylated antibody fragments by site-specific modification using cysteine-selective PEG derivatives. The conjugates showed long *in vivo* half-lives and full retention of antigen-binding properties. A cysteine residue was also inserted into anti-HIV protein cyanovirin-N by site-directed mutagenesis, followed by chemical reaction with thiol-specific PEG derivatives [42]. The resulting conjugates were highly active, whereas nonspecific modification with PEG resulted in a total loss of antiviral activity.

PEG-aldehyde derivatives have been used to selectively modify N-terminal amino groups of proteins [2, 17, 43]. For example, PEGylated granulocyte colony stimulating factor (GCSF) was prepared using PEG-aldehyde derivatives that were attached to the N-terminal methionine residue [44, 45]. The reaction mixture contained more than 80% of the intended conjugates with preserved biological activity. PEGylated GCSF is currently approved by the FDA for clinical use.

4.5.2.2 Immunogenicity

Although recent advances in the recombinant DNA technology have allowed production of several proteins in large quantities, their applications are frequently limited due to immunogenic responses by the body. For example, recombinant human interleukin-2 (rhIL-2), expressed and purified from *Escherichia coli*, has received attention as an anticancer therapeutic agent. However, some patients undergoing clinical trials with rIL-2 have reported to develop antibodies to the protein [9]. It is also known that repeated administrations of human insulin, produced by genetic engineering, resulted in generation of antibody [46]. Immunogenicity of recombinant human proteins can lead to serious clinical consequences. Antibody binding to a protein may change its pharmacokinetics in the body [47]. Antibody formation can inhibit the therapeutic effect of proteins and/or neutralize the essential endogenous proteins. Long-term administration of recombinant

human erythropoietin to patients induced formation of antibody capable of neutralizing endogenous erythropoietin [48, 49]. PEGylation has shown to suppress such adverse effects of recombinant proteins [18, 50]. In their pioneering studies on PEGylation, Abuchowski et al. demonstrated that administration of native albumin to rabbits resulted in rapid removal of protein by immuno-complex formation, whereas PEGylated albumin showed long circulation in the bloodstream [18]. Although a few references indicate generation of antibodies to PEG [5, 51], it is generally accepted that generation of anti-PEG antibodies is practically negligible, mainly due to its weak immunogenicity and the low amounts of PEGylated conjugates in clinical trials.

Suppression of immunogenicity by PEGylation is primarily based on shielding of the epitope (immunoreactive site) of a protein by flexible PEG chains. Improved immunological properties alter the pharmacokinetic profile of the modified protein. For example, when IgG was intravenously administrated to monkeys, it was cleared rapidly because of an antiprotein immune response [52]. On the other hand, PEGylated IgG did not elicit an immune response, and their dose levels were 125% as compared with the native antibody. This indicated that PEGylation of a protein increases the circulation time in the bloodstream by reducing clearance by the immune system.

The extent of suppression of immunogenicity is known to depend on the PEG molecular weight, number of grafted PEG chains, conjugated sites, and PEG architecture (linear or branched) [46, 53]. Protein immunogenicity is generally reduced as the number of PEG, and its molecular weight increases. Conjugation of branched PEG is reported to be more effective than linear PEG in improving immunological and pharmacokinetic properties of the modified proteins. Asparaginase modified with 10-kDa PEG reduced the antigenic character by 10-fold, as compared with that of the same protein modified with 5-kDa PEG [46]. Branched PEG could reduce immunogenicity of uricase more efficiently than linear PEG [54]. The author suggested that the "umbrella-like" structure of branched PEG efficiently prevented the approach of antiprotein antibodies and immuno-competent cells (Figure 4.5-2). It

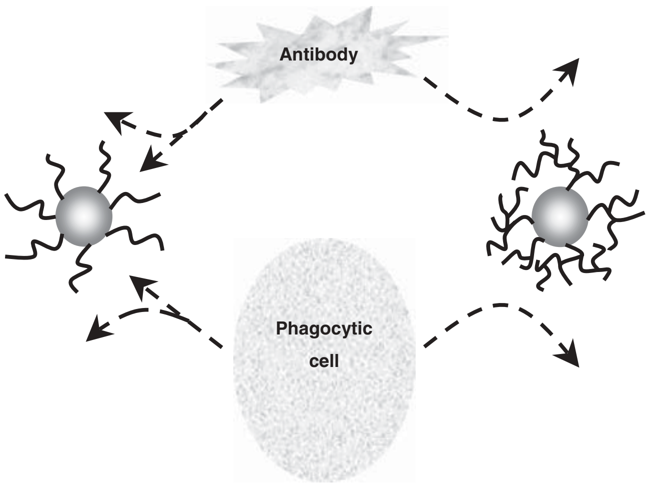

Figure 4.5-2. Molecular architectures of PEG grafted on proteins. The branched PEG protects more effectively from antibodies, phagocytic cells, and enzymes.

would be preferred to attach the PEG chains around the antigenic epitopes, if this does not deteriorate the biological activity of the protein [50].

4.5.2.3 Clinical PEGylated Proteins

In the early 1990s, two PEGylated proteins, PEG-adenosine deaminase (Pegademase) and PEG-L-asparaginase (Pegaspargase), were approved by the FDA as therapeutic agents replacing the parent compounds. Recently approved PEGylated protein drugs include Pegfilgrastim, Peginterferon alfa-2a, and Peginterferon alfa-2b. More than 20 PEGylated proteins are on the market or in clinical trials, as shown in Figure 4.5-3 [4, 17].

Pegademase was developed for the treatment of severe combined immunodeficiency (SCI), which is associated with an inherited deficiency of adenosine deaminase [55]. SCI patients are conventionally treated by transfusing red blood cells containing adenosine deaminase. However, the patients often suffer from iron overload and transfusion-associated viral infections [56, 57]. Use of Pegademas does not need to consider such adverse effects and allows minimizing the dose of therapeutic agents. L-Asparaginase has been used for treatment of acute lymphocytic leukemia, acute lymphoblastic leukemia, and chronic myelogenous leukemia. L-Asparaginase, however, requires frequent intramuscular injections and often induces allergic reactions [58]. Compared with unpegylated L-asparaginase,

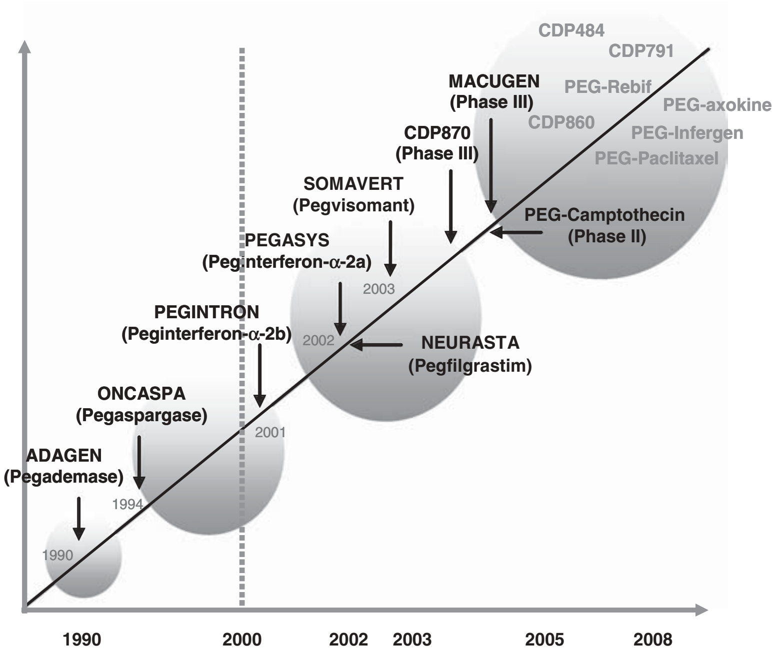

Figure 4.5-3. PEGylated products on the market or under clinical development. Since the first PEGylated protein was introduced, Pegademase (Adagen) entered the market in 1990 followed by a growing stream of PEGylated pharmaceuticals, as symbolized by circles in the figure. In 2004, a total of 26 PEGylated pharmaceuticals were on the market or under clinical trials.

Pegaspargase showed a substantially prolonged half-life. The half-lives of L-asparaginase and Pegaspargase were 20 and 357 h, respectively [59]. PEGylation of L-asparaginase also reduced adverse immune responses [58]. Although the actual cost of Pegaspargase is higher than that of multiple injections of unpegylated L-asparaginase, en-hanced therapeutic effects and minimal complications may make overall the cost considerably less than that of conventional therapy.

Interferon-based therapeutic drugs have been approved for treatment of various diseases, such as chronic hepatitis B and C, renal cell carcinoma, chronic myelogenous leukemia, and malignant melanoma. However, the clinical use of interferon has been limited because of rapid absorption from the subcutaneous injection site, large volume of distribution, rapid clearance via the kidney, short serum half-life (~6 h), and significant side effects such as depression and flu-like symptoms [60]. Interferons were initially PEGylated using a small, linear PEG (MW = 5 kDa) at multiple sites via the urea linkage [61]. These conjugates were not suitable for further clinical applications because of pharmacokinetics needed to be improved. Interferon alfa-2b was then modified with longer PEG (MW = 12 kDa) by forming a degradable linkage to improve the therapeutic effect [62]. The result was Peginterferon alfa-2b, which showed a long half-life with clinical efficacy, and is now marketed for treatment of chronic hepatitis C. The next generation of PEGylated interferon was interferon alfa-2a modified with a branched 40-kDa PEG via formation of an amide linkage [63]. The resulting Peginterferon alfa-2a allowed sustained delivery of the protein and showed the ability to be detected in the serum for longer than 1 week. It is interesting to note that the different chemical linkages of the two PEGylated interferons led to different formulations for the market. Peginterferon alfa-2b is available as a lyophilized powder, thus requiring reconstruction before use. On the other hand, Peginterferon alfa-2a is provided as a ready-to-use solution because the conjugates are linked by a stable amide bond.

Several PEGylated proteins are currently undergoing clinical trials. PEGylated human growth hormone antagonist (Pegvisomant) is being tested for treatment of acromegaly. Pegvisomant has been approved in Europe and is waiting for FDA approval in the United States. The PEGylated inhibitor of tumor necrosis factor-alpha is being tested for the treatment of rheumatoid arthritis and Crohn's disease [64]. Patients treated with the PEGylated protein experienced improvement in physical function, pain, vitality, and mental health [65].

4.5.3 PEGYLATED CELLS

4.5.3.1 Immunocamouflage of Cells

Immunological recognition of allogeneic tissues is a primary concern in transfusion and transplantation medicine. Graft-versus-host-disease (GVHD) is induced by the transfer of allogeneic lymphocytes into immunocompromised individuals [66]. GVHD can cause significant morbidity and mortality among patients with tissue transplantation. Several pharmacological agents that inhibit the T-cell signaling and activation have been developed such as cyclosporine, azathioprine, and methotrexate [67]. However, these drugs are less than optimal due to their substantial toxicity.

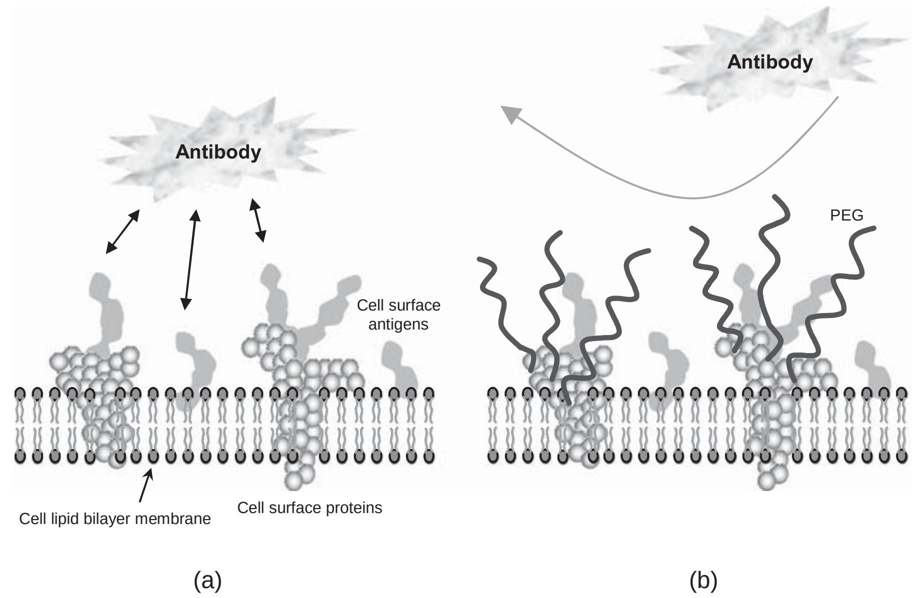

Figure 4.5-4. Immunocamouflage of cells by PEGylation: (A) Cell membrane containing surface antigens causes immune reactions, which destroy the transplanted cells. (B) PEGs grafted on the cell surface cytoprotect against antibodies.

Scott et al. [68–74] suggested a new method that can significantly diminish rejection episodes and may further enhance the induction of tolerance. They have demonstrated that the surface engineering of cells by PEGylation yielded antigenically and immunogically inert cells. Figure 4.5-4 schematically illustrates immunocamouflage of cells by surface PEGylation. The mechanisms underlying immunocamouflage by PEGylation are the loss of antigen recognition, impaired cell–cell interaction, and an inability of endogenous antibodies to effectively recognize and bind foreign epitopes. As a result of the high molecular flexibility and intense hydration, the grafted PEG can sterically block off a large three-dimensional volume thereby giving immunoprotective effects to membrane proteins and carbohydrates.

4.5.3.2 Red Blood Cells (RBCs)

Blood transfusion is a widely used therapy in medicine, particularly under surgery and trauma conditions. Surface engineering of red blood cells (RBCs) by PEGylation has been studied to camouflage the blood group antigens from their antibodies, thereby to generate universal RBCs. Several studies demonstrated that the surface engineering of RBCs with PEG significantly attenuated immunologic recognitions of surface antigens [68–71, 73–75]. PEGylation significantly decreased binding of human RBC blood group antibody and phagocytic destruction by heterologous phagocytes [68], PEGylation also dramatically diminished the immunogenicity of allogeneic and even xenogeneic RBCs in mouse models [71]. Importantly, this protective immunologic effect can be accomplished without adversely affecting

the structure, function, or viability of the modified RBCs. PEGylation was found to have no significant detrimental effects on the RBC structure or function. PEGylation did not affect RBC lysis, morphology, and hemoglobin oxidation state. The functional aspects of the PEGylated RBCs were also maintained, as evidenced by normal oxygen binding and cellular deformability [71].

The immunocamouflage efficacy is largely dependent on the PEG grafting density, PEG length, and tomography of the membrane surface. Differently functionalized PEGs have been used to chemically graft PEG onto the membrane of cells. Typical functionalized PEGs include PEG-dichlorotriazine [68], PEG-benzotriazole carbonate [73], and PEG-succinimidyl succinate [73]. They all preferentially target the ε-amino group of exposed lysine residues on membrane proteins. PEG-dichlorotriazine is the most common reagent. PEGylation of RBCs with PEG-dichlorotriazine has been shown to mask Rh antigens to a reasonable extent, but masking of antigen A or B was partial. Recently, Nacharaju et al. suggested a new approach for PEGylation of RBC proteins using thiolation-mediated maleimide chemistry [75]. In the study, masking of blood group antigens was not directly correlated to the PEG-grafting density or PEG chain length. For optimizing the masking of A, B, D, and CE antigens, a combination of different size PEG chains was used. PEG-5000 (molecular weight of PEG 5 kDa) alone masked the most important antigens of the Rh system (C, c, E, e, and D) from their antibodies. However, the masking of the A and B antigens needed a combination of PEG-20000 and PEG-5000 to inhibit agglutination of RBCs completely with anti-A or anti-B [75]. Recently, another strategy for RBC PEGylation was suggested by Chung et al. [76]. RBC PEGylation was carried out by incorporation of lipid-PEG into RBC membranes. The incorporation was rapid and spontaneous at room temperature. No change was observed in the membrane shape of the lipid-PEG incorporated RBC. The incorporation of lipid-PEG dramatically attenuated the antigenic recognition of RBC. As many as 35% of individuals with sickle cell disease or thalassemias exhibit clinically significant alloimmunization to non-ABO antigens [77, 78]. Immunocamouflage of RBCs by PEGylation may significantly attenuate the risk of alloimmunization for patients requiring chronic RBC transfusions such as patients with sickle cell anemia and thalassemias.

4.5.3.3 White Blood Cells

T-lymphocytes play a central role in immune responses. Transfusion or transplantation of T lymphocytes into an allogeneic recipient can evoke potent immune responses. Extensive attention has been paid to inactivation of T cells as well as other leukocytes (B lymphocytes, mononuclear cells, and granulocytes) from blood products. PEGylation dramatically blocked allorecognition and proliferation in human peripheral blood mononuclear cells (PBMCs) and isolated murine splenocytes [69, 72, 79–81]. Loss of cellular proliferation was not due to cytotoxicity of grafted PEG but to the global camouflage of the cell surface, which inhibited cell–cell interactions. T-cell and antigen-presenting cell adhesion molecules (CD2, CD11a), signaling molecules (CD3ε, T-cell receptor), and costimulatory molecules (CD28, CD80) were efficiently camouflaged by PEGylation [81]. Immunocamouflage was clearly observed in murine models of transfusion-associated graft versus host disease (TA-GVHD) [81]. Mice receiving saline or the PEGylated splenocytes

exhibited an identical survival curve, whereas mice receiving control splenocytes (unmodified) showed significant TA-GVHD. This improved survival was directly associated with the donor cell proliferation. Unmodified control splenocytes showed significant proliferation due to allorecognition of the host mice. In contrast, PEGylated cells failed to proliferate due to immunocamouflage and lack of allorecognition, indicating that PEGylation of donor splenocytes significantly decreased donor T-cell proliferation, thereby suppressing GVHD.

4.5.3.4 Pancreatic Islets

Transplantation of pancreatic islets has been one of the most challenging examples of tissue transplantation. Insulin-dependent diabetes mellitus (IDDM) is a disease from the autoimmune destruction of β cells of the islets of Langerhans in the pancreas. Tranplantation of islets into diabetic patients can be the most attractive mode of treatment, but the islets must be protected from the host's immune system to prevent graft rejection. Transplanted islets are recognized by host as antigens that activate immune cells, such as macrophages, granulocytes, and lymphocytes. Several studies demonstrated that camouflage of pancreatic islets by PEGylation could be an attractive approach to prevent activation of immune cells and secretion of cytokines, thereby improving transplantation of pancreatic islets [82–87].

PEG chains were covalently conjugated to the amino groups of collagen capsules of islet at physiological conditions through a stable amide bond [84]. PEG was not grafted onto the inner islet cell membrane but directly onto the collagen matrix of islet. Therefore, PEGylation did not damage the inner islet cells. Cell viability and functional activity remained intact after PEGylation. When free islets were cultured with lymphocytes, they completely lost the integrity of the collagen capsule [86]. The co-cultured lymphocytes were activated by free islets, thereby secreting a large amount of IL-2 and TNF-α cytokines. In contrast, the PEGylated islets were not damaged by co-culture with lymphocytes. The co-cultured lymphocytes were not activated by the PEGylated islets and rarely secreted IL-2 and TNF-α cytokines, suggesting that the grafted PEG effectively prevented cell–cell interaction necessary for the allogeneic rejection. The PEGylated islets were not affected by macrophoages, either. However, when co-cultured with lipopolysaccharide (LPS)-stimulated macrophages (activated macrophages), the PEGylated islets lost the integrity of the collagen capsule and were completely destroyed. Once macrophages are activated, they secrete several kinds of cytotoxic molecules, such as IL-1β, TNF-α, and nitric oxide (NO). Complete destruction of PEGylated islets indicates that the grafted PEG could not prevent infiltration of the cytotoxic molecules into the islets [84, 86].

4.5.4 COLLOIDAL NANOPARTICLES WITH PEG-EXPOSED SURFACES

At the interface of nanotechnology and biotechnology, nanosized colloidal particles (nanoparticles) have emerged as a new entity with great potential for target-specific therapy and imaging [88–90]. The fundamental advantages of colloidal nanoparticles for drug delivery result from their two main basic properties. First,

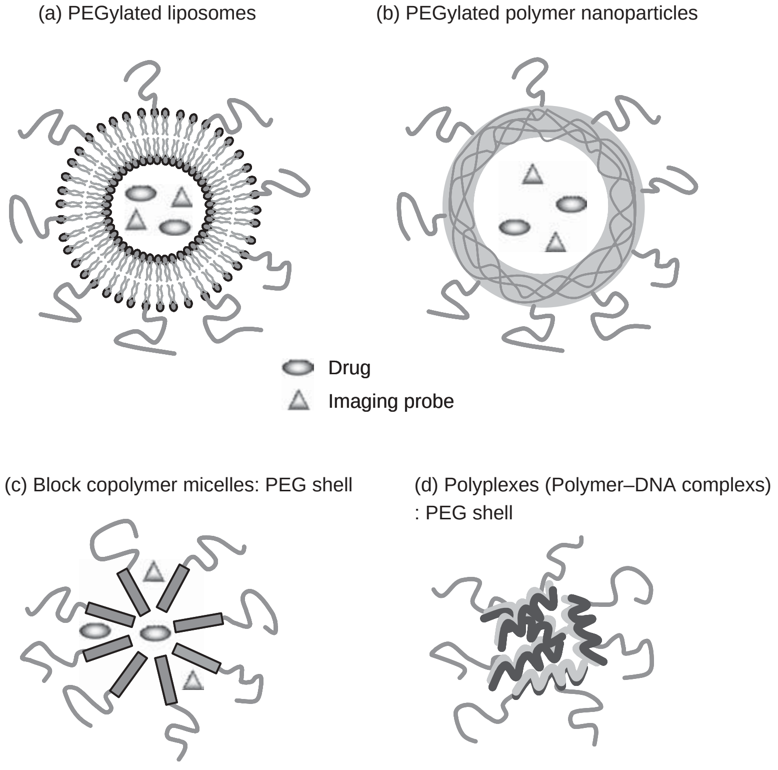

Figure 4.5-5. Colloidal nanoparticles with PEG-exposed surfaces.

nanoparticles due to their small size can penetrate through capillaries and are taken up by cells, and this allows efficient drug accumulation at the target sites. Second, nanoparticles allow sustained drug release within the target site over a period of days or even weeks. Thus, nanoparticles could be effective delivery systems for therapeutic and imaging payloads. However, intravenously injected nanoparticles are also treated as foreign by the host, just like exogenously delivered proteins and cells. The nanoparticles should avoid recognition by the cells of the reticuloendothelial system (RES), namely macrophages of the liver, spleen, lungs, bone marrow, and lymphnodes. Adsorption of plasma proteins onto the surface of nanoparticles is also highly problematic for efficient delivery of drugs and diagnostic agents. As a result, there has been a growing interest in the surface engineering of colloidal nanoparticles to avoid rapid recognition by RES and to reduce adsorption of plasma proteins. These systems are often called "Stealth" nanoparticles, which are "invisible" to macrophages and have a prolonged half-life in the blood circulation. PEGylation has been increasingly exploited to camouflage colloidal nanoparticles against recognition by the body's defenses. Figure 4.5-5 schematically represents different colloidal nanopaticles with the PEG-exposed surface.

4.5.4.1 Stealth Liposomes

Development of PEGylated liposomes, also known as "stealth" liposomes, greatly broadened the application of liposomes. For incorporation of PEG into the

liposomal bilayer, various functionalized lipids have been developed that contain a primary amino group, an epoxy group, or a diacylglycerol moiety [91, 92]. Alternatively, activated PEGs were anchored to reactive phospholipids groups of preformed liposomes [93]. In most cases, PEGylated liposomes with prolonged circulation time are in the size range of 70 to 200 nm and contain 3–7 mol% of PEG in addition to various amounts of phospholipids and cholesterol. The circulation half-lives of such stealth liposomes are 15–24 h in rodents and as high as 45 h in humans. In addition to PEG, various hydrophilic polymers have been grafted onto liposomes for prolonging the circulation time. They include polyvinylpyrrolidone, poly(vinyl alcohol), poly(2-methyl-2-oxazoline), poly(2-ethyl-2-oxazoline), polyacrylamide, poly(acryloyl morphine), and N-(2-hydroxylpropyl)methacrylamide copolymers [92, 94–98].

4.5.4.2 Polymeric Nanoparticles

Surface engineering of polymeric nanoparticles with PEG has been performed by physical adsorption, by incorporation during production of nanoparticles, or by covalent attachment to the surface. Typical examples of PEG-conjugated polymeric nanoparticles are PEG-poly(L-lactic acid) (PLA), PEG-poly(l-lactic-co-glycolic acid) (PLGA), PEG-poly(ε-caprolactone) copolymers, and PEG-polyphosphazene [92]. Although *in vitro* physico-chemical characterization studies, such as measurement of hydrodynamic volume and protein adsorption, have confirmed the steric barrier effects of PEG, the circulation half-lives of these nanoparticles were not as long as expected, generally less than a few hours. Many polymeric nanoparticles with a promising outlook based on *in vitro* results have faced the same problems when tested *in vivo*. Furthermore, little information is known with regard to the colloidal stability of nanoparticulate systems *in vivo* and their extent of interaction with blood and cellular components. This is an area that needs more understanding for effective use of nanoparticles.

4.5.5 CONCLUSIONS

PEGylation offers significant pharmacological advantages to proteins, cells, and colloidal nanoparticles. PEGylation improves protein solubility and molecular stability, and it reduces protein immunogenicity. By preventing rapid renal clearance, PEGylation extends the circulating life of proteins, thus allowing longer duration of action. PEGylation greatly enhances the clinical value of therapeutic proteins. Indeed, many PEGylated proteins have entered the market or are under clinical trials. PEGylation provides a unique strategy in avoiding immunological recognition of allogeneic cells and tissues. The global camouflage of the cell surface by PEGylation effectively blocks adhesion, recognition, and stimulatory pathways involved in the immune response. More importantly, unlike most therapeutics, PEGylation is nontoxic to modified cells as well as to the animal as a whole. PEGylation provides colloidal nanoparticles with a way to avoid rapid recognition by RES. PEGylation reduces deposition of plasma proteins to the surface of nanoparticles and thereby prolongs the circulating time in the bloodstream. Indeed, development of the PEGylation technology has been a cornerstone of the advances

in protein therapeutics. Not only has this technology brought numerous clinically useful products, but also triggered explosive interest in polymers in the field of pharmaceutical biotechnology.

4.6.1 INTRODUCTION

Recombinant human erythropoietin (rHuEPO) is a purified glycoprotein produced by recombinant DNA technology. It is indistinguishable from human urinary erythropoietin in its biologic and immunologic activity. It is commercially available and has absolute indications for the treatment of the anemia associated with chronic renal failure, prematurity, and platinum-based chemotherapy. Other uses have included the anemia associated with multiple myeloma, cancer, myelodysplasia, HIV infection, and other forms of chemotherapy. It has been used to potentiate preoperative autologous blood donation. Less common uses have been in the treatment of the anemia of chronic disease, for perisurgical augmentation and after allogenic bone marrow transplantation [1].

Endogenous erythropoietin (EPO) is produced primarily by the peritubular capillary endothelium of the kidney in response to tissue hypoxia or anemia. EPO is a

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

hormone that plays a crucial role in the regulation of hematopoiesis and induces the proliferation, maturation, and differentiation of erythroid (red blood cell) precursors. In renal failure, the nonfunctioning kidneys fail to produce adequate amounts of endogenous EPO to support erythropoiesis with resultant anemia. Before the introduction of exogenous erythropoietin in the 1980s, patients in renal failure required repeated blood transfusions.

After 1998 there was a significant increase in the number of cases of pure red cell aplasia (PRCA) associated with subcutaneous injections of rHuEPO in the renal dialysis population. PRCA is a relatively rare condition. It presents as a sudden onset of severe isolated anemia characterized by near-complete absence of erythroid precursors in the bone marrow [2]. Most of the initial reports in the literature before 1998 involved isolated cases, of which 50% had no known cause. After 1998, the PRCA was shown to be related to neutralizing antibodies to erythropoietin that cross-reacted with endogenous EPO [3]. Most of these reported antibody-mediated cases were for patients using Eprex (Ortho Biotech, a division of Janssen-Cilag, Bridgewater, NJ). In total between January 1, 1989 and June 30, 2004, the company reported a total of 206 cases, of which 155 occurred in the peak years of 2001–2003 [4]. The mean time from initial exposure to onset of PRCA was 9.1 months [5].

The rise in cases of PRCA corresponded with the introduction of polysorbate 80 stabilized Eprex in prefilled syringes with uncoated rubber stoppers, which was administered subcutaneously. Previously human serum albumin (HSA) was used to stabilize the product, but this practice was discontinued in several countries due to fears of disease transmission by HSA. Epidemiologic and immunologic data reported by Boven et al. [4] demonstrated that the rise in PRCA was most likely related to leachates from the uncoated stoppers in the presence of the polysorbate 80 stabilizer. These leachates may have potentiated the immunogenicity of the product when administered subcutaneously.

No cases for intravenous administration were reported. Since the introduction of coated stoppers in the prefilled syringes in April 2003 and a concomitant switch to intravenous administration in many dialysis units, the number of reported cases fell from 71 in 2003 to 2 reported cases in the first 4 months of 2004. Even at its peak, the incidence rate for PRCA was relatively low at 4.61/10,000 patient years of exposure to the product.

4.6.2 ERYTHROPOIETIN AS A POTENTIAL GROWTH FACTOR IN WOUND HEALING

In addition to its ability to stimulate erythropoiesis, EPO enhances cell phagocytosis and reduces macrophage activation, therefore modulating the inflammatory process. These anti-inflammatory effects of EPO may be able to reverse the chronic inflammatory condition that is believed to underlie chronic skin ulcers. By interfering with the chronic inflammatory process EPO may help reduce inflammatory cytokines and degradative enzymes that interfere with many wound healing processes and limit new tissue growth. Recent literature suggests that many chronic wounds persist because of inflammatory processes that alter the wound environment. Analysis of wound fluid taken from healing and chronic wounds revealed

that chronic wounds have elevated levels of inflammatory mediators and degradative enzymes that interfere with the healing process [6]. Healing wounds are characterized by high mitogenic potential, rapid cellular migration, balanced inflammatory cytokines, low proteases, and good cellular response to growth factors. Chronic wounds, however, are characterized by poor mitogenic potential and cell migration, high proteases and inflammatory cytokines, and senescent cells unresponsive to growth factors [7]. EPO's effects on the wound healing process not only include restoring the normal wound environment, but it also has recently been found to interact with vascular endothelial growth factor (VEGF). Together EPO and VEGF stimulate endothelial cell mitosis and motility important in new vessel growth and wound healing [8]. Galeano et al. [9] demonstrated in an artificial wound model in genetically diabetic mice that erythropoietin injections increased VEGF mRNA expression, wound protein content, wound healing, and wound breaking strength. The additional benefits of EPO are its neurotrophic and neuroprotective functions that may ameliorate neurological damage after spinal cord and brain injury [10]. A specific EPO/EPO receptor system has been found in the central nervous system and in the cerebrospinal fluid, which is independent of the heatopoietic system [11].

Chronic skin ulcers experienced by patients who have low concentrations of circulating hemoglobin (≤100 g/L) may be difficult to heal because of impairment in tissue oxygenation. There are various types of anemias with differing underlying causes, including nutrient deficiencies, such as iron deficiency anemia, and anemia as the result of chronic disease or chronic inflammatory processes. Iron deficiency anemia results from inadequate intake, absorption, or utilization of iron and/or acute or chronic blood loss [12, 13]. It is characterized by low hemoglobin and other hematological changes combined with microcytic, hypochromic red blood cells. There are low levels of stored iron as indicated by low serum ferritin values. Anemia of chronic disease (ACD) is characterized by low hemoglobin concentrations and other hematological changes with normocytic, normochromic red blood cells. In anemia of chronic disease, red blood cell production is impaired and there may be a shortened red blood cell life span. ACD is also characterized by a normal or elevated serum ferritin level. ACD is generally not an irondeficiency anemia, and it is refractory to an iron-enhanced diet, iron replacement therapy, either oral or intravenous, and transfusion. In fact, iron supplementation and transfusion are generally contraindicated in ACD because of the risk of iatrogenic hemochromatosis. ACD occurs in individuals with a chronic inflammatory process such as arthritis, critical illness, or chronic skin ulcers. It is thought to be the result of impaired responsiveness of erythroid progenitor cells due to a persistent elevated level of circulating inflammatory cytokines that are known to occur in patients with chronic inflammatory conditions [14]. Ferrucci et al. [15] demonstrated in a study of inflammatory serum markers in a sample of the residents of Chianti Italy that the anemia of inflammation evolved from a pre-anemic state in which normal hemoglobin was maintained in persons with high levels of inflammatory markers by increasing levels of erythropoietin to a clinical anemia in which erythropoietin levels were suppressed possibly through the inhibitory effect of inflammation on erythropoietin production.

However, despite the numerous documented effects of EPO on cellular and physiological events known to be important in the healing process and the

management of ACD, few clinical studies are investigating the use of EPO to promote the healing of chronic wounds. In 1992 Turba et al. reported the successful treatment of ACD related to stage IV pressure ulcers [16]. In another hematological disorder, treatment with EPO resulted in the rapid and complete healing of chronic leg ulcer, further improvement in hematological parameters, and relief from chronic pain [17].

4.6.3 CLINICAL EXPERIENCE WITH RECOMBINANT HUMAN ERYTHROPOIETIN AND PATIENTS WITH PRESSURE ULCERS

Spinal cord-injured patients are at high risk of developing pressure ulcers, many of which often become associated with anemia of chronic disease. These ulcers are challenging to heal. Pressure redistribution, nutritional support, management of incontinence, and good local wound care are key components for healing these ulcers. Despite best-practice care, patients with anemia of chronic disease remain difficult to heal.

In an attempt to reverse the anemia of chronic disease, several patients in the Spinal Cord Injury rehabilitation unit at Parkwood Hospital, St. Joseph's Health Care, London, Canada, were treated with subcutaneous erythropoietin. A retrospective chart audit was conducted to review the effectiveness of 6 weeks of subcutaneous erythropoietin 75 IU/kg subcutaneously 3 times weekly in resolving refractory anemia of chronic disease and healing stage IV pressure ulcers [18]. The mean age of the patients was 59, and all had a stage IV pressure ulcer.

All patients received pressure off-loading, nutritional assessment and supplementation, and best-practice local wound care. Comorbid conditions such as diabetes were medically managed. All patients received rHuEPO 75 IU/kg subcutaneously three times weekly for 6 weeks. Iron supple-mentation with oral ferrous gluconate as indicated by ferritin levels was administered.

Mean initial hemoglobin was 88 g/L. After 6 weeks of rHuEPO injections, the mean hemoglobin for the four patients rose to 110 g/L. The individual results are shown in Figure 4.6-1. The mean number of ulcers decreased from 3 to 2.3, and

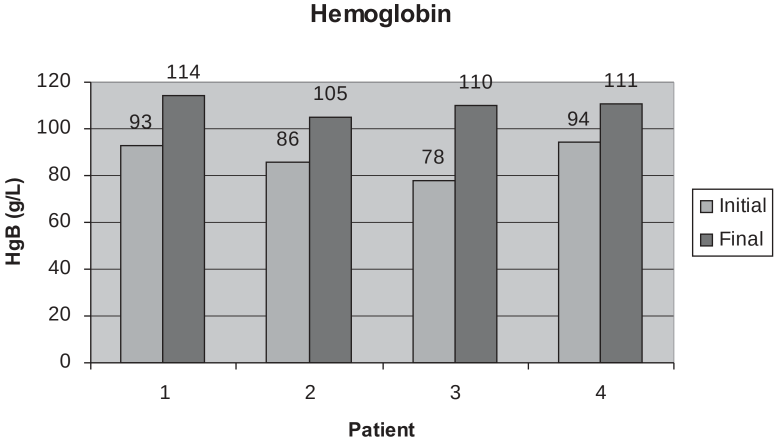

Figure 4.6-1. Comparison of initial and final hemoglobin after 6 weeks rHuEPO.

the mean surface area of the largest ulcer decreased from 42.3 cm^2 to 38.4 cm^2. Ulcer depth was decreased by half. The extent of undermining improved in all ulcers. Some patients showed an increased ability to fight intercurrent infections. All patients felt more energetic and were better able to participate in their rehabilitation activities. No adverse effects were observed.

The results were promising enough to suggest that a prospective study is warranted. Such a study would carefully collect all hematologic factors as well as use validated tools for determining ulcer size and appearance. In addition, collecting wound fluid before, during, and after treatment to determine the effect on chronic inflammatory mediators would be useful. Research into effects at the molecular level may be useful.

4.6.4 CONCLUSIONS AND FUTURE RESEARCH

The introduction of human recombinant erythropoietin significantly improved the quality of life for patients on real dialysis by managing the concomitant anemia, which results from end-stage renal failure. It has also been successfully employed in several other conditions in which erythropoiesis is suppressed either through disease processes or as a result of treatments.

The emergence of pure red cell aplasia as a complication of treatment with subcutaneous injection in the late 1990s was probably the result of the use of prefilled syringes with uncoated rubber stoppers in which the product was stabilized with polysorbate 80. Leachates from the stoppers most likely potentiated the immunogenicity of the product leading to the production of neutralizing antibodies. Since the reformulation of the product, the incidence of PRCA has been steadily dropping.

Human recombinant erythropoietin shows promise in resolving the refractory anemia of chronic disease associated with stage IV pressure ulcers, and further study is suggested. The results may also suggest that rHuEPO acts as a growth factor either alone or in conjunction with intrinsic factors in the wound. Studies of its role at the molecular level are indicated. Further studies of the neurotrophic and neuroprotective properties observed in rat models hold promise in the area of spinal cord injury research.

5.1.1 INTRODUCTION

Capillary electrophoresis (CE) is a modern analytical method that is being extensively applied to the characterization of biotechnology-derived products like peptides and proteins [1]. Due to its ease of automation and facilitating the development of reproducible routine analysis, CE seems to be well suited for the quality control of biotechnological products, including process monitoring, purity assessments,

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.
Copyright © 2007 John Wiley & Sons, Inc.

and stability studies [2]. Moreover, the high-resolution capacity of CE offers great potential for the analysis of heterogeneous protein products such as glycoproteins and polymer-conjugated proteins [3, 4]. Recently, the importance of CE in protein analysis is enhanced, with efforts being made to learn more about the compositions and functions of proteins [5]. As the field of proteomics becomes more important, the thousands of new proteins and peptides will be discovered, which will lead to the developments of many new pharmaceutical drugs.

Recently, CE has emerged as a powerful tool because it has many advantages over the conventional protein separation techniques such as polyacrylamide gel electrophoresis (PAGE) and high-performance liquid chromatography (HPLC). Compared with PAGE, CE is faster, easier, simpler, quantitative, and has automation capability. Like HPLC, CE has various different separation modes and is applicable to a wide range of analytes. CE requires a very small sample amount (nanoliters) and limited quantities of reagents (microliters of buffer), compared with HPLC that requires microliters of sample and milliliters of solvent. The main advantage of CE over PAGE and HPLC is the ability to produce a higher number of theoretical plates. The efficient separations result from the application of high electric fields (100–500 V/cm) and flat flow generated by the electro-osmotic flow (HPLC generates the pressure-driven parabolic flow). The high electrical resistance of a capillary and its favorable surface area-to-volume ratio, permitting efficient heat dissipation, enables the application of high electric fields without causing detrimental heat generation. Furthermore, the mild separation conditions of CE, which use mostly aqueous buffer solutions, present the compatibility to protein studies in native state, which can be important especially in the characterization of pharmaceutical proteins. The main disadvantage of CE is the low concentration limits of detection due to the short path length and the limited introduction of sample volume. The enhancements in this issue have been achieved by the advent of several preconcentration methods [6] and highly sensitive detection methods such as laser-induced fluorescence and mass spectrometry [7].

This chapter introduces the fundamental principles of CE and its application to the separation and characterization of peptides and proteins. One major characteristic of CE is the availability of various separation modes with different separation mechanisms based on the differences in charge-to-mass ratio (capillary zone electrophoresis), molecular size (capillary gel electrophoresis), isoelectric point (capillary isoelectric focusing), and hydrophobicity (micellar electrokinetic capillary chromatography and capillary electrochromatography). In the principles of CE, the instrumentation, theory, separation modes, and detection methods are described focusing on the analysis of peptides and proteins. In applications, CE methods for identification, purity assessment, heterogeneity characterization, and stability of peptide and protein products are highlighted with the characterization of Poly(ethylene glycol) (PEG)ylated biomolecules. Finally, the role of CE in proteomics research is discussed with the recent approaches.

5.1.2 PRINCIPLES OF CAPILLARY ELECTROPHORESIS

5.1.2.1 Instrumentation

The main components of a CE system are a high-voltage power supply, a capillary, inlet and outlet buffer vials, a detector, and a data output and handling device such

as an integrator or computer (Figure 5.1-1A). A variety of commercial instruments are available with different capabilities, including injection methods, detectors, capillary cooling systems, and software [8]. CE is performed by filling inlet and outlet vials and the capillary with an electrolyte, usually an aqueous buffer solution. Electrodes connected to a high-voltage power supply are then immersed in the vials. Very small amounts of sample are introduced into one end of the capillary, and these are driven electrophoretically down the lumen of the capillary toward the opposite electrode. The species that migrate through the capillary are detected by an online optical detector near the capillary outlet, and these data are displayed as an electropherogram, in which separated compounds appear as peaks with different migration times.

Fused silica capillaries of length of 20–100 cm and inner diameters of 50–100 μm are typically used. The outer surface of capillary is coated with polyimide, which is strongly ultraviolet (UV) absorbent. A detection window can be made by simply burning or scraping off a small section of the polyimide outer capillary coating. This section of the capillary is then placed in the light path of the detector, and thus solutes are detected while in the capillary. Most commercial instruments have a capillary cartridge, which retains the capillary, provides mechanical support, and allows the capillary to be consistently aligned at the optical center of the detector. Cartridges are used in conjunction with cooling systems, which maintain capillary temperatures using coolant or cooled air.

Only a few microliters of sample are required for CE because usually only 1–50 nanoliters of sample are injected into a capillary. For example, a 50-μm inner diameter capillary 50 cm long has a volume of only ca. 1 μL [9]. Samples are injected

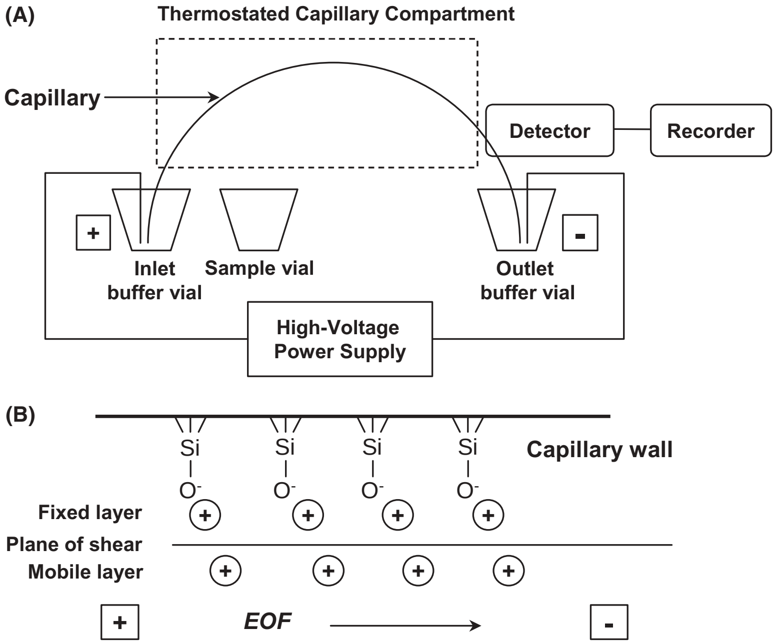

Figure 5.1-1. Schematic diagram of a capillary electrophoresis system (A) and electroosmotic flow (EOF) (B).

into capillaries using different techniques, such as hydrodynamically or electrokinetically. Hydrodynamic injection can be performed by pressure or siphoning. Pressure injection is performed by either pressurizing the sample vial or by applying a vacuum to the outlet vial. Siphon injection is performed by raising the sample vial, which causes the sample to be siphoned into the capillary. In electrokinetic injection, an electric field is applied to the sample vial, causing the sample components to migrate into the capillary. Most commercially available instruments have autosamplers into which several sample vials can be loaded. The samples are then automatically injected into capillaries using one or more of the techniques above.

A variety of detectors have been used for CE, including UV absorbance, fluorescence, laser-induced fluorescence, and mass spectrometry. The most widely used is the UV absorbance detector. In some cases, two or more detectors are connected in series. A more detailed the description of the detection system is given in Section 5.1.2.4.

The power supply provides an electric field across the capillary with voltages up to 30 kV, currents up to 300 μA, and power up to 6 W. Most instruments can be operated in either constant voltage, constant current, or constant power mode and have a reverse applied polarity facility. The constant voltage mode is most commonly used. It is necessary to have a stable voltage, as any variations in voltage will cause changes in migration times.

Most CE systems are controlled by an external computer that controls all instrumental functions. The operating parameters for each analysis are programmed by computer. The electropherograms obtained are plots of detector response versus time; thus, they resemble familiar HPLC or gas chromatography (GC) chromatograms, which means that familiar data handling systems can be used. In addition, electronic integrators or computers are used for qualitative identification and quantitation, as in HPLC or GC.

5.2.2.2 Theory

Electrophoresis is the phenomenon whereby ionic species in a conductive aqueous medium moves under the influence of an electric field. Thus, ionic molecules are separated due to differences in their electrophoretic mobilities. The electrophoretic mobility (μ) of a spherical ion is given by

$$\mu = q/6\pi\eta r$$

where q is the charge of the ion, η is the viscosity of the solution, and r is the hydrodynamic radius of the ion. This equation demonstrates the positive relation between charge-to-mass ratio (q/r) and electrophoretic mobility. The electrophoretic migration velocity (ν) depends on the electrophoretic mobility (μ) and the applied electric field (E):

$$\nu = \mu E$$

Besides the electrophoretic migration, a fundamental electrophoretic phenomenon occurring in CE is the electro-osmotic flow (EOF), which essentially is an electrical field-driven bulk solution flow from the anode to the cathode (Figure 5.1-1B). This flow occurs because acidic silanol groups on the inside of fused-silica

capillary are ionized when in contact with buffer solution. At pH above 3, these silanol groups are deprotonated and form an electric double layer. When an electric field is applied, the net positively charged solution in a capillary moves toward the cathode. EOF is highly dependent on buffer pH; i.e., it increases on raising pH and plateaus at about pH 8, but it is not significant below pH 4. At neutral and higher pH, the EOF is sufficiently strong to allow all molecules, regardless of charge, to move toward the outlet and pass the detector. EOF can be effectively controlled by changing several experimental conditions, including separation buffer pH, ionic strength, addition of organic solvents, and buffer additives. The apparent migration velocity of the analyte depends on their electrophoretic mobility (μ_e), electro-osmotic mobility (μ_{eo}), the applied voltage (V), and capillary length (L):

$$\nu = (\mu_e + \mu_{eo})V/L$$

The electrophoretic mobility of peptides and proteins was first described by Offord [10], who proposed the following equation, which relates the mobility (μ) with valence (Z) and molecular mass (M):

$$\mu = k\text{ZM}^{-2/3}$$

where k is an empirical constant. This equation states that frictional forces opposing electrophoretic migration are proportional to the surface areas of the species concerned. This implies that the electrophoretic mobility would be proportional to $1/r^2$ ($1/\text{M}^{2/3}$), rather than $1/r$ ($1/\text{M}^{1/3}$), which is suggested by the Stoke's model. This relationship was later confirmed and modified by several researchers in the CE field [11, 12]. Janini et al. presented the electrophoretic mobilities of 58 peptides that varied in size from 2 to 39 amino acids and in charge from 0.65 to 7.82 [13]. Figure 5.1-2 shows CE separation of several peptides in a 50-mM phosphate buffer

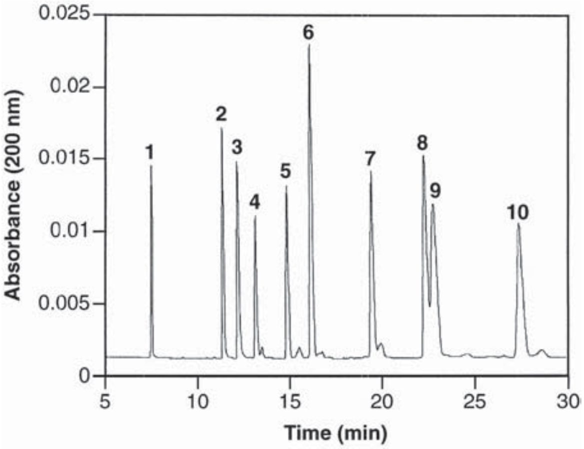

Figure 5.1-2. Electropherogram of a mixture of bioactive peptides separated at pH 2.5. Peptides: (1) reference; (2) bradykinin; (3) bradykinin fragment 1–5; (4)substance P; (5) [arg]–vasopressin; (6) luteinizing hormone releasing hormone; (7) bombesin; (8) leucine enkephalin; (9) methionine enkephalin; (10) oxytocin. at pH 2.5. The electrophoretic data were used to test existing theoretical models that correlate electrophoretic mobility with physical parameters. The best fit of the experimental data was obtained with the Offord model that correlates electrophoretic mobility with the charge-to-size parameter $q/M^{2/3}$.

5.1.2.3 Separation Modes

As HPLC has different separation modes of chromatography, including adsorption, partition (normal and reversed phase), ion-exchange, size-exclusion, and affinity, CE also has various separation modes, e.g., capillary zone electrophoresis (CZE), capillary gel electrophoresis (CGE), capillary isoelectric focusing (CIEF), micellar electrokinetic capillary chromatography (MEKC), and capillary electrochromatography (CEC) (Table 5.1-1). Moreover, these different CE separation modes can be used to complement each other, and thus, they greatly enhance the versatility of the technique. In many cases, it seems that no single method can separate peptides and proteins because these biomolecules are diverse and complex in terms of structure and composition. Therefore, different optimal strategies involving different CE separation modes are often used to solve the separation problems.

Capillary Zone Electrophoresis (CZE). CZE is a widely used CE technique and separates peptides and proteins based on differences in their charge-to-mass ratios. Separations occur in a capillary filled with a buffer of constant composition. For CZE, the run buffer choice is extremely important because it determines the charge on the analyte molecule and its migration rate. Thus, the type of buffer, its ionic strength, and its pH are optimized for particular separation problems. Buffers based on sodium phosphate, citrate, acetate, or combinations thereof with concentrations ranging from 10 to 200 mM are frequently used [14].

TABLE 5.1-1. Separation Modes of CE for the Characterization of Peptides and Proteins

Technique	Separation Mechanism	Applications	Conventional Technique
CZE	Charge-to-mass ratios	Peptide mapping, purity and stability of peptides and proteins, and glycoprotein heterogeneity	—
SDS–CGE	Molecular size	Estimation of relative molecular mass of protein (10–200 kDa) and purity and stability of peptides and proteins	SDS–PAGE
CIEF	Isoelectric point (p*I*)	p*I* determination of proteins, purity of proteins, and glycoprotein heterogeneity	Gel IEF
MEKC	Hydrophobicity	Purity of peptides and glycoprotein heterogeneity	RP–HPLC
CEC	Hydrophobicity	Peptide mapping and purity of peptides	RP–HPLC

Proteins contain both positively and negatively charged functional groups. The positively charged moieties in proteins, such as the guanidinium group of arginine residues, the amino groups of lysine residues and N-termini, and histidine residues, interact with negatively charged silanol groups on capillary walls at pH values above 3. These interactions between proteins and capillary walls (protein adsorption) lead to sample loss, peak broadening, poor resolution, and longer migration times.

Many strategies devised to overcome protein–wall interactions have focused either on selecting separation buffer conditions that reduce protein binding sites or on treating capillary surfaces to reduce interaction sites [15]. By using separation buffers with extreme pH values (e.g., below pH 2~3 or above pH 10), protein adsorption can sometimes be reduced. At pH values below around 2, the silanol groups of the capillary are fully protonated and surface charge approaches zero, whereas at pH values above 10, capillary surfaces are completely deprotonated and highly anionic. In these situations, protein adsorption is significantly reduced because of electrostatic repulsion. However, operations at extreme pH conditions can be problematic in finding suitable separation conditions due to reduction of differences of analytes in effective electrophoretic mobility. At low pH, EOF is negligible, making separations slow, and at high pH, EOF is generally high and resolutions are reduced. Additional problems encountered under extreme pH conditions include the effect on protein conformational changes. Unfolding or aggregation of proteins may occur, resulting in irreproducible data, often reduced efficiency, and a loss of biological activity. Therefore, the use of this approach is limited to a few selected applications.

To optimize separation conditions at moderate pH conditions, surface modifications of capillary can be helpful [16]. Such modifications can decrease protein–surface interactions by reducing the surface charge of the silica material. Several approaches have been proposed for modifying the inner walls of capillaries, such as chemical coating with bonded/cross-linked polymers, physical adsorption coating with cationic polymers, and dynamic coating with adsorbed surfactants. The most popular coating method is to covalently bind polymers such as polyacrylamide or poly(vinyl alcohol) to capillary walls [17]. Chemically coated capillaries are widely used and are available commercially. The preparations of this capillary type often involve several chemical reactions that may cause large variances between capillaries. In addition, these coatings are usually stable in restricted pH ranges and have limited lifetimes. Noncovalent capillary coatings are simply formed by treating the capillary with one or more charged polymers that are physically adsorbed onto internal walls. Initially, positively charged monolayer coatings of polybrene [18], polyethyleneimine [19], or poly(diallyldimethylammonium chloride) [20] were used. More recently, noncovalently bilayer-coated capillaries prepared by add anionic polymer to cationic polymer-coated capillary have been reported to be long-lived and to have an EOF that is stable over wide pH ranges (2–11) [21]. Katayama et al. reported on the use of a polymeric bilayer of polybrene and dextran sulfate for the separation of some model proteins [22]. Catai et al. demonstrated the use of capillaries coated with a bilayer of polybrene and poly(vinyl sulfonate) for the fast, highly reproducible, and efficient analysis of peptides and proteins [23, 24]. Another way of coating capillaries is to add the coating agents (usually low-molecular-weight compounds such as amines and surfactants) to the separation buffer for the dynamic coating of the inner capillary surface [25].

Sodium Dodecyl Sulfate-Capillary Gel Electrophoresis (SDS–CGE). SDS–CGE is a capillary-based version of SDS–polyacrylamide gel electrophoresis (SDS–PAGE) in the slab gel format, with advantages of shorter analysis times, ease of automation, and online detection and quantitation [26, 27]. In SDS–CGE, replaceable sieving polymers, such as linear polyacrylamide, poly(ethylene oxide), dextran, or pullulan, are used to achieve reproducible separations. These polymers permit the replacement of a separation matrix for each sample, thereby eliminating cross-contamination between samples and improving reproducibility. Best results are often obtained using chemically or dynamically coated capillaries.

For SDS–CGE, proteins are denatured and complexed with SDS before analysis. These SDS–protein complexes are then separated based on their sizes. The molecular mass of an unknown protein can be estimated by running protein standards as well. This assumes that migration is dependent on relative mass, on the basis of the following two assumptions. First, all SDS–protein complexes have the same charge-to-mass ratio in the presence of excess SDS (~1.4 g of SDS/1 g of protein). Second, the SDS–protein complexes have similar shapes, and thus, their sizes are linearly related to their molecular masses. However, these assumptions are not valid for some classes of proteins, e.g., basic proteins, hydrophobic membrane proteins, and glycoproteins, because deviations from predicted charge-to-mass ratio are often observed for their SDS–protein complexes. For example, basic proteins have lower charge-to-mass ratios because of the presence of positively charged amino acids, whereas hydrophobic membrane proteins have larger charge-to-mass ratios. Moreover, in the case of glycoproteins, the carbohydrate moieties do not bind with SDS, and this lowers the charge-to-mass ratio, leading to a decreased migration and overestimation of molecular mass [3, 28]. Figure 5.1-3 shows the SDS–CGE result for ricin toxin purified from the seeds of the castor bean (*Ricinus communis*) [29], in which two peaks of ricin toxin were partially separated, while only a single band appeared in the SDS–PAGE gel. Two peaks were identified to be ricin glycoform isomers with identical protein sequences but with different carbohydrate contents. When the molecular masses of two peaks were determined with a calibration curve made by protein standards (MW 14–200 kDa), they were significantly higher than those measured by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI–TOF MS). This shows the slower electrophoretic migration of glycoproteins in SDS-based gel electrophoresis compared with that of standard proteins. However, the presence of carbohydrate may improve the resolution between glycoforms in SDS–CGE [29].

In addition to the estimation of protein molecular mass, SDS–CGE is also the common choice for checking the presence of other proteins, protein aggregates, or protein degradation products during characterization, purity, or stability studies.

Capillary Isoelectric Focusing (CIEF). CIEF separates peptides and proteins according to isoelectric point (p*I*) differences. Proteins that differ by 0.005 p*I* units or even less have successfully been separated by CIEF. The sample is normally mixed with ampholytes (zwitterionic compounds), which have slightly different p*I* values spanning the desired pH range and act as a strong buffer at their p*I* values and then the capillary is filled with this mixture. The capillary inlet is placed in a vial containing acidic solution (anolyte) and the capillary outlet in a basic solution (catholyte), before applying an electric field. A pH gradient is quickly formed by

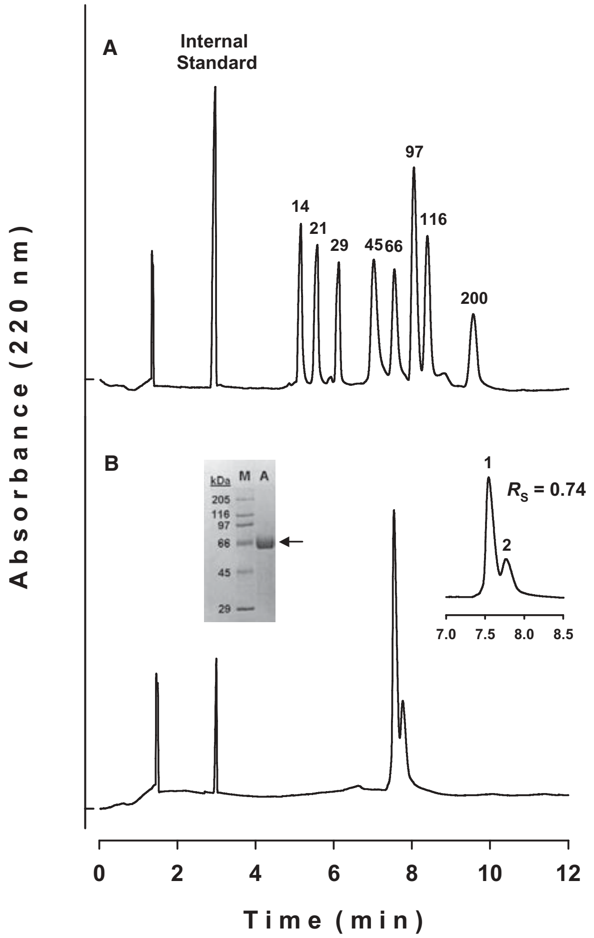

Figure 5.1-3. SDS–CGE electropherograms of molecular weight standard marker (14–200 kDa) (A) and ricin toxin glycoprotein under nonreducing conditions (B). The right insert is an enlargement of ricin peaks in SDS–CGE, presenting the partially separated two peaks ($R_s = 0.74$) compared with only a single band shown in the SDS–PAGE gel. (Reprinted from Ref. 29, with permission.)

the ampholytes ranging from low to high pH along the entire capillary length. According to their electrophoretic mobilities, proteins migrate to their p*I*s in the capillary where they are focused into very sharp zones. The overall focusing process can be monitored by observing current changes, which approach zero when ion movement inside a capillary stops. The CIEF process can be performed in one or two steps. One-step CIEF is performed in an uncoated capillary and usually employs polymers such as hydroxypropyl methyl cellulose or hydroxyl ethyl cellulose in order to reduce but not eliminate EOF [30]. At this point, either migration past a detection window or whole-column imaging is needed to visualize the separation [31]. In two-step CIEF, proteins are first focused in a coated capillary to eliminate EOF and then mobilized by adding a salt (sodium chloride) to the catholyte or by applying pressure to the capillary inlet (anolyte) [32, 33]. In general, the two-step

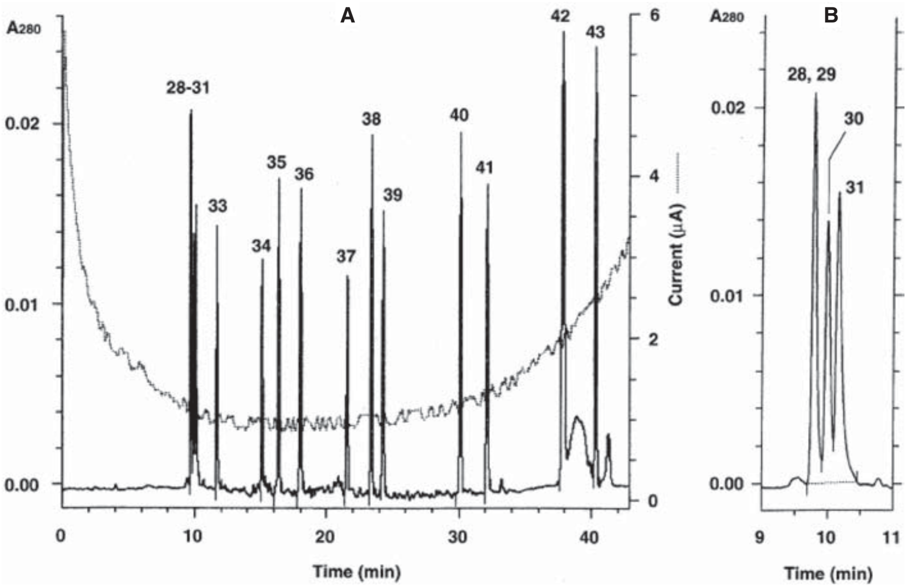

Figure 5.1-4. CIEF separation of the peptide p*I* markers ranging from pH 3.38 (peptide #43) to 10.17 (peptide #28). (B) Enlargement of the portion from 9 to 11 min of (A). (Reprinted from Ref. 35, with permission.)

method is preferred because it provides a much higher reproducibility [34]. As CIEF is usually run from positive to negative polarity, the most basic proteins pass the detector first. Absorbance must be monitored at UV 280 nm to avoid the strong absorption of ampholytes at lower wavelengths. The use of a coated capillary is required for high resolution because EOF interferes with maintenance of focused zones.

The estimation of p*I* in CIEF needs appropriate p*I* markers. Synthetic peptide and oligopeptide p*I* markers for CIEF with UV absorption detection have been developed [34]. Shimura et al. proposed a set of 16 synthetic oligopeptides as p*I* markers for CIEF that are fully compatible with UV detection [35]. Figure 5.1-4A shows the CIEF separation of 16 p*I* markers ranging from pH 3.38 (peptide number 43) to 10.17 (peptide number 28). Figure 5.1-4B is an enlargement of the region between 9 and 11 min, showing partial resolution of high p*I* markers and the overlap between peptide numbers 28 and 29 due to a lack of extension of the pH gradient toward more alkaline pH values. CIEF produces the best resolution for proteins and peptides among the CE separation modes, and it is a powerful tool for resolving modified proteins, for characterizing microheterogeneity, and for identifying glycoforms [36]. CIEF has also been found to be a powerful tool in proteomics studies [37].

Micellar Electrokinetic Capillary Chromatography (MEKC). MEKC separation is based on the partition of analytes between micelles and the surrounding aqueous phase [38]. This technique can be considered a type of chromatography where the stationary phase is essentially mobile and the mobile phase is electro-osmotically

pumped. The micellar phase is composed of a surfactant added to the buffer above its critical micellar concentration (CMC). The most commonly used surfactants are SDS, bile salts, and hydrophobic chain quaternary ammonium salts. In general, neutral or alkaline buffer solutions are used to create a strong EOF that moves even anionic micelles in the capillary toward the cathode.

MEKC has been applied with great success to the analysis of a variety of small molecules. However, relatively few protein applications have been found for MEKC [39, 40], which may be because most proteins (>MW 5000) are too large to partition into the hydrophobic core of micelles. However, proteins can associate with micelles through hydrophobic, hydrophilic, and electrostatic mechanisms, and these interactions have been exploited to manipulate protein separation using MEKC [41]. By manipulating these protein–micelle interactions using the variables, such as surfactant concentration, pH, ionic strength, and the addition of an organic modifier, MEKC has been demonstrated to resolve proteins with minor structural variations and to allow the quantitative analysis of proteins present in complex matrices [3].

Capillary Electrochromatography (CEC). Capillary electrochromatography (CEC) is a hybrid technique of CE and HPLC that is generally carried out using packed capillary columns by the electro-osmostically driven mobile phase at high electric field strength. CEC has been rapidly developed in recent years as it has combined advantages of both techniques, i.e., the high selectivity of HPLC and the high efficiency of CE, with minimum consumption of both reagents and samples, and good compatibility with mass spectrometry [42]. The separation mechanism involved is based on chromatographic retention, and for charged analytes, on a combination of this and electrophoretic mobility. Initially, CEC was mainly used to separate neutral compounds such as polyaromatic hydrocarbons. Recently, the successful development of CEC column technology and improvements in instrumentation have encouraged research on CEC for peptide and protein separations [43]. Various capillary columns have been used for peptide and protein analysis, including packed capillaries, open-tubular capillaries, and monolithic columns.

In addition to the use of octadecylsilane (ODS) as a stationary phase, sulfonated poly(styrene-divinylbenzene), poly(2-sulfoethylaspartamide)-silica, open tubular silica, porous styrenic sorbents and octadecylsilica, pentofluorophenylsilica, tryconsilica, octadecylsilica, acrylate-based porous monoliths, and wide-pore stationary phases have been recently investigated [44, 45]. CEC separations using monolithic columns are being actively investigated because the stationary phases are easily prepared and supporting frits are unnecessary. In monolithic columns, the stationary phase is covalently bound to inner capillary walls. CEC separations of peptides and proteins in monolithic columns are usually performed in counter-directional mode; i.e., peptides and proteins migrate electrophoretically in a direction opposite to the EOF [46, 47].

Recently, a great deal of interest has been shown in the combination of CEC and mass spectrometry (MS) because CEC is considered to overcome many of the limitations of other CE techniques [48–50]. When combined with electrospray ionization (ESI)–MS, CZE is limited to a small number of buffer systems and suffers from low sample loading capacity. MEKC has relatively poor selectivity and

difficult compatibility with MS because it requires the use of high surfactant concentrations. In contrast, CEC has good compatibility with MS, selectivity, sample loading capacity, and general applicability.

5.1.2.4 Detection

In the CE system, peptides and proteins are typically detected by UV absorbance, laser-induced fluorescence (LIF), or MS. UV absorbance is the most widely used detection method, but when higher sensitivity is required, LIF or MS are preferred. Recently, MS is being increasingly used to detect peptides and proteins separated by CE with the improvement of proteomics research.

UV Absorbance. UV detection of peptides and proteins is mostly performed at 200–220 nm, where the absorption is proportional to the number of peptide bonds, but sometimes around 254 or 280 nm, where the detection is based on the absorbance of the aromatic residues such as tryptophan, tyrosine, and phenylalanine. This detection method is most commonly used, but it has low sensitivity, which is a major disadvantage for the detection of analytes present at low concentrations. In CZE, UV detection is limited to micromolar or submicromolar concentrations for peptides and proteins. Several capillaries have been designed to improve the sensitivity in CE: (1) a rectangular capillary extended in the direction of the light path [51], (2) a Z-shaped capillary [52], and (3) a bubble cell capillary with an locally enlarged diameter in the detection region [53]. These capillaries help somewhat to improve sensitivity, but practical difficulties of availability and implementation into existing instruments remain.

Laser-induced Fluorescence (LIF). Fluorescence is inherently a sensitive detection method with lower detection limits than UV absorbance detection. In addition, fluorescence detectors are selective because only fluorescing molecules are detected. Typical detection limits of fluorescence detection lie in the range 10^{-7}–10^{-9} M. The light sources used are usually deuterium, tungsten, or xenon lamps. Lasers are also good sources of high-intensity radiation and are used for LIF detection. LIF is the most sensitive detection method in CE. Detection limits of LIF have been reported to fall in the range 10^{-18}–10^{-21} M [54–56]. A variety of lasers have been employed for the detection of peptides and proteins, which include Nd:YAG, argon ion, helium–cadmium, and helium–neon lasers. As proteins containing aromatic amino acid residues (tryptophan, tyrosine, and phenylalanine) have native fluorescence around 310 nm, the intrinsic fluorescence has been directly measured using Nd:YAG at 266 nm or helium-cadmium at 320 nm as a laser source [57, 58]. However, these systems are expensive and the helium–cadmium lasers have a problem of short lifetimes [59]. The most popular lasers for the detection of peptides and proteins are argon lasers at 488 and 514 nm and helium–neon lasers at 544, 593, and 633 nm that are relatively inexpensive, stable, and compact. However, they are often not suitable for exciting most proteins to induce native fluorescence. To overcome this disadvantage, the labeling of the molecules with a suitable fluorescent dye is required via pre-column, on-column, or post-column. Several fluorescence-labeling reagents are commercially available and conveniently used for peptides and proteins. Rhodamine, solvatochromic dyes (SYPRO Red, Nile Red), and

Albumin Blue 580 have been used to form stable and highly fluorescent complexes with proteins [59].

Mass Spectrometry (MS). MS is an important and powerful detection tool for the characterization of peptides and proteins by CE, as evidenced by recent developments of CE–MS methodology and its applications [60, 61]. MS detection considerably enhances the utility of CE by providing information about the identity of the separated molecules. The availability of CE–MS is also highly desirable for purity and stability studies of peptide and protein drugs. Especially, in proteomics, peptidomics, and peptide mapping, the importance of both on- and offline coupling of MS with CE separations of peptides and proteins is greatly growing [62].

The introduction of soft ionization techniques such as ESI and MALDI brought tremendous progress in on- and offline characterization of electrophoretically separated peptides and proteins by MS [50]. Combination of CE with MS techniques allows not only high-accuracy molecular mass determination of peptides and proteins separated by CE, but also it provides important structural data on amino acid sequence, the sites of posttranslational modifications, peptide mapping, and the noncovalent interactions of peptides and proteins.

ESI forms gaseous ions by applying a strong electric field to a fine spray of their liquid solutions. It allows the generation of multiply charged ions, which enables the detection of very large molecules even with instruments having a low mass range. The multiply charged peaks can be transformed into a singly charged peak by mathematical deconvolution, which enables the determination of the molecular weight of the original species. ESI is the preferred mode for online coupling CE with MS because molecules can be transferred directly from the capillary to the mass spectrometer via an interface. Three types of interfaces, i.e., sheathless, liquid–junction, and coaxial liquid sheath-flow, have been constructed for CE–ESI–MS coupling [63].

In MALDI, the analyte is cocrystalized with the matrix (small organic compounds having strong absorbance in the laser wavelength) and a laser beam is directed onto this crystal, causing vaporization of the matrix and desorption of the ions. The main advantage of MALDI is the generation of predominantly single-charged molecular ions of even macromolecules with a molecular mass up to 300 kDa with the exact determination of molecular mass with accuracy of ±0.1%. Therefore, the MALDI–MS is a more attractive option for the characterization of heterogeneous samples [7]. The MALDI–MS is combined with CE separations of peptides and proteins more in an offline mode than with an online liquid sample delivery connection [64]. In offline mode, fractions separated from the CE are collected and deposited on a MALDI target in the form of spots for MS analysis. Recently, approaches for the online coupling of CE with MALDI–MS have been developed to minimize sample handling and potential losses [65, 66].

5.1.3 APPLICATIONS

In pharmaceutical biotechnology, the development of analytical procedures to validate identity, strength, quality, and purity of biopharmaceutical products is one of the most important issues for the production of highly specialized biotechnology

products, as described in the U.S. Food and Drug Administration's (FDA's) current Good Manufacturing Procedures (cGMP) requirements for drugs (Title 21 of the Code of Federal Regulations, Parts 210 and 211). In this chapter, we discuss the use of CE to assess the identity, purity, heterogeneity, and stability of peptides and proteins, and its applications of CE in proteomics research.

5.1.3.1 Identity Determination

The identity of peptides and proteins can be determined by specific activity assays, determination of amino acid composition and sequence, and assessment of such physico-chemical parameters as molecular mass and p*I*. Several CE techniques have been used for the identity of peptides and proteins, which include peptide mapping by CZE or CEC, CIEF for the determination of protein's p*I*, SDS–CGE for the determination of relative molecular masses of proteins, and CE–MS for direct molecular mass assignment of peaks separated by CE.

Traditionally, IEF and SDS–PAGE in slab gel systems have been routinely used to confirm the identity of the proteins. CE formats, CIEF and SDS–CGE, offer fast and reproducible separations and direct online detection without the need of staining and destaining procedures used in slab gel techniques. As a typical example, Hunt et al. showed CIEF and SDS–CGE methods for the qualitative analysis of recombinant humanized monoclonal antibody HER2 (rhuMAbHER2) [67]. The CIEF separated five charged isoforms of rhuMAbHER2 with estimated p*I* values in the range of 8.6–9.1. These results agreed well with the p*I* values determined on slab gel IEF. In SDS–CGE, the expected molecular masses of intact rhuMAbHER2 under nonreduced conditions and its heavy-chain and light-chain fragments under reduced conditions were identified with good correlation with SDS–PAGE analysis. This study demonstrated the feasibility of replacing the slab gel techniques with CE methods in a quality control environment.

CE–MS. In SDS–PAGE, the molecular mass of proteins is estimated based on comparison with reference proteins with relatively poor accuracy of ±5–10% [68]. When proteins are extracted from slab gels and subsequently transferred to ESI–MS or MALDI–MS, the mass accuracy somewhat improves, but the methodology still suffers from the interferences originated from gel [50]. Frequently, accurate molecular mass determination is necessary especially for the identification of unambiguous peptides and proteins. Since its introduction in 1987 by Olivares et al. [69], CE coupled to MS has gained increasing attention in peptide and protein research because of the CE ability to separate analyte from complex mixtures with high efficiency and minimal sample consumption. In CZE–ESI–MS, mass accuracies down to 0.0008% have been realized for model mixtures of proteins [70].

Tsuji et al. reported CZE–ESI–MS for the analysis of recombinant bovine and porcine somatotropins (rbSt and rpSt) [71]. The average molecular masses of rbSt and rpSt were determined to be 21,812.6 and 21,798.3, which were nearly identical to the theoretical values of 21,812.0 and 21,797.9, respectively. Yeung et al. reported on the CE–ESI–MS method for the analysis of high-mannose glycoproteins, ribonuclease B, and recombinant human bone morphogenetic protein-2 [72]. CE separations were performed with 50-mM beta-alanine buffer (pH 3.5) in a

polyacrylamide-coated capillary and a coaxial sheath–liquid interface was used for CE–MS coupling. The identities of glycoform peaks separated by CE were determined by the combination of UV and MS detection data without the need of oligosaccharide release or derivatization treatments.

Na et al. reported on an offline combination of CZE and MALDI–TOF MS for the identification of salmon calcitonin (sCT) acylation products formed in the degrading poly(lactic-co-glycolic acid) (PLGA) microsphere formulations [64]. As shown in Figure 5.1-5, the peptides extracted from sCT microspheres incubated in drug release medium were analyzed by both CZE with UV detection (200 nm) and MALDI–TOF MS. After the incubation, the additional peak was observed in CE (Figure 5.1-5c) and mass peaks of m/z 3491.15 and 3549.16 except the intact sCT were presented in MALDI–TOF MS spectrum (Figure 5.1-5d). The identities of two peaks separated in CE (Figure 5.1-5c) were confirmed by reanalysis of each peak fraction using MALDI–TOF MS, which was also used for the quantitation of peptide loaded into microsphere formulations [73].

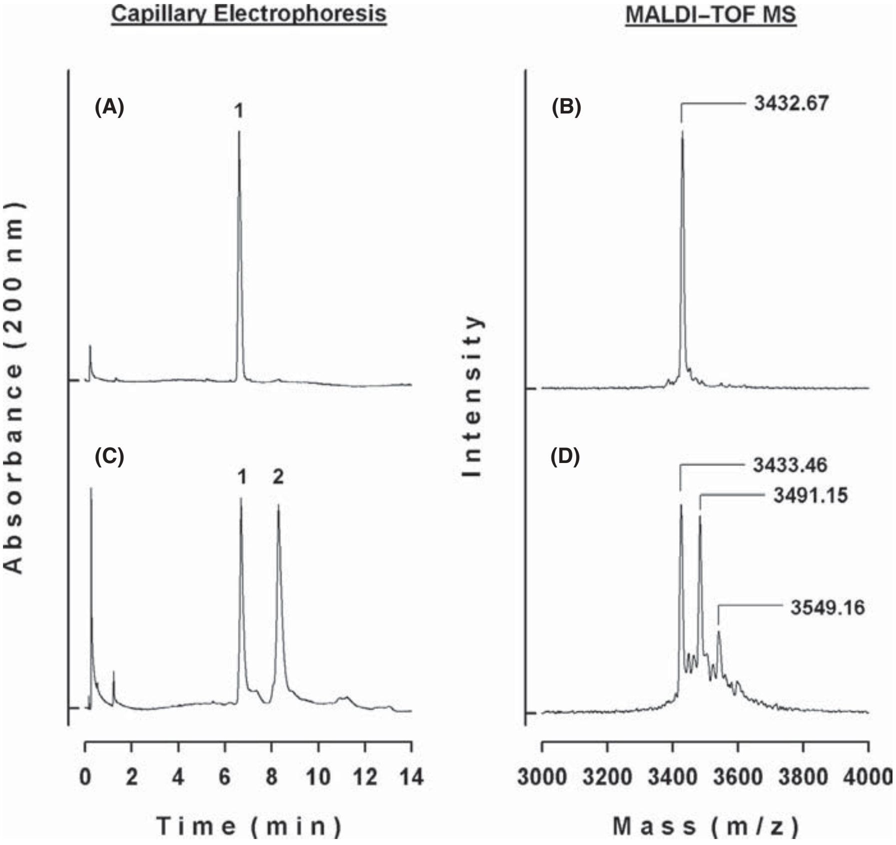

Figure 5.1-5. CZE and MALDI–TOF MS analysis of sCTs extracted from microsphere at 0 day (A and B) and 21 days (C and D) of incubation in release medium at 37°C. In the CE electropherogram, peak 1 is native sCT and 2 represents the degradation products. (Reprinted from Ref. 64, with permission.)

Recently, a variety of peptides and proteins were analyzed by CE–MS techniques, which include CZE–MALDI–TOF–MS, CZE–ESI–MS, CIEF–ESI–MS, and CEC–ESI–MS. Their applications are well summarized in a recent review paper [50].

Peptide Mapping. Peptide mapping is an important tool for protein identif-ication, primary structure determination, the detection of posttranslational modifications, the identification of genetic variants, and the determination of glycosylation and/or disulfide sites. For these reasons, peptide mapping is widely used for quality control and for the characterization of recombinant DNA-derived products. Moreover, the high resolution of CE makes it a powerful peptide mapping technique.

Rush et al. (1993) reported on the CE-based peptide mapping of recombinant human erythropoietin (EPO) derived from Chinese hamster ovary (CHO) cells. Using 100-mM heptanesulfonic acid in 40-mM sodium phosphate buffer (pH 2.5) as a separation buffer, this technique showed a baseline separation of 16 tryptic-digested peptides with one partial separation of two peptides [74]. This peptide map demonstrated the structural differences between the glycosylated form expressed in CHO cells and the non-glycosylated form expressed in *E. coli*, and it provided information on the heterogeneity in glycoforms of EPO. Zhou et al. presented the results of the CE–ESI–MS analysis of tryptic digests of EPO, and they found that the technique is complementary to HPLC–ESI–MS [75]. Boss et al. reported on an evaluation of CE–MS for the peptide mapping of EPO [76]. In this study, tryptic-digested peptides were first separated by reversed-phase (RP)–HPLC and collected fractions were analyzed by offline and online CZE–MS experiments employing a capillary coated with Polybrene in the presence of polyethylene glycol and 0.67-M formic acid as a separation buffer.

Despite the impressive ability of CE to separate peptides, a complete separation of all digested peptides is unlikely to be achieved because of the highly complex natures of the peptide maps of large proteins. Recently, multidimensional separations, such as two-dimensional (2D) electrophoresis, HPLC–CZE, HPLC–MS, CZE–MS, and HPLC–CZE–MS, have been applied for complete resolution of highly complex peptide mixtures [77]. A sequential offline combination of RP–HPLC and CZE was used for the peptide mapping of pepsin isoenzymes, recombinant human tissue plasminogen activator, cytochrome c, and myoglobulin [78–80]. Kang et al. presented unique "fingerprint" peptide maps of two closely related proteins, β-lactoglobulins A and B, by combining CZE separations performed in four different channels and MEKC separations performed in two different channels in a 96-capillary array [81]. He et al. developed a novel multiplex CE system for the high-throughput comprehensive peptide mapping of proteins [82]. By using multiple separation conditions using six CZE buffers and two MEKC buffers in a 20-capillary array, the peptide fragments of proteins digested by three different enzymes were readily resolved and showed unique fingerprints. These 20 capillaries were monitored simultaneously at 214 nm using a single photodiode array detector, and the overall analysis time from reaction to detection was about 40 min.

5.1.3.2 Purity Control

Purity control is necessary on peptide and protein products for process and quality control purposes [83–85]. Minor amounts of impurities and degradation products

must be determined in the presence of much larger quantities of primary components. These components may be structurally very similar to the main component. CE can be applied as a sensitive control method for such determinations because it provides rapid and accurate qualitative and quantitative data on peptide and protein preparations.

Peptide Purity. Peptide purity checks have been routinely performed by RP–HPLC. Recently, CE has increasingly been used as a versatile technique for the analysis of peptide drugs in the pharmaceutical industry [84]. Because of the different separation mechanisms, CZE is recognized as an excellent complementary tool to RP–HPLC. CZE separates the peptide based on differences in mass-to-charge ratios, whereas RP–HPLC separation is per-formed based on hydrophobicity differences. Peptides with similar hydro-phobicities, which are difficult to be separated by RP–HPLC, can often be resolved based on charge-to-mass ratio differences. Therefore, peaks that appear pure by RP–HPLC are often resolved in multiple peaks by CZE. Moreover, CZE requires only nanoliter quantities of sample so that almost all of the sample can be used for subsequent sequence analysis.

Ridge and Hettiarachchi reported on CZE separations of bradykinin and its impurities using phosphate buffers at various pH values (pH 2.5, 3.5, and 4.5), which were not fully resolved by HPLC [86]. When buffer pH was increased from 2.5 to 4.5, several impurities were well separated from the major peak of bradykinin. In purity checks of peptide, the similar superiority of CZE over RP–HPLC is also found in publications by Chen et al. [87], Hettiarachchi et al. [88], and Moumakwa et al. [89].

Protein Purity. During the production of recombinant proteins, process monitoring is required to assure purity levels required in every step. The recovery and purification of product from fermentation broth typically involve various procedures, such as filtration, centrifugation, and chromatography. After each purification and final step, constituent levels must be determined to ensure that the desired levels of purity have been achieved. In addition to its control function, this purity information is also frequently used to further optimize purification processes. CZE and SDS–CGE can be mostly used for the purity checks of protein products.

Several CZE methods were reported for the purity determinations of recombinant human insulin. Human insulin consists of two peptide chains, A (21 amino acids) and B (30 amino acids), which are connected by two disulfide bonds. To determine the purity of insulin, two main degradation products, acidic and neutral desamido-insulin (desamidated at positions A-21 or A-21 and B-3, respectively), should be separated from the main compound [90]. According to U.S. Pharmacopoeia (USP), the relative amount of desamido insulin must not exceed 3% of the total amount of insulin and desamido insulin [91].

A CZE method for the separation of insulin and its deamidation products with untreated fused-silica capillaries using a run buffer containing 2-(*N*-cyclohexylamino) ethanesulfonic acid (CHES), triethylamine, and 10% acetonitrile has been reported [90]. This system separated acidic and neutral desamido-insulin in formulated human insulin with the relative standard deviation (RSD) of the migration times ≤1%, whereas RP–HPLC coeluted the neutral desamido-insulin with insulin. Sergeev et al. described an analytical scheme for monitoring recombinant human

insulin during the various steps of its production [92]. The CZE method has been included, together with narrow-bore HPLC and MALDI–TOF MS, in the analytical scheme for monitoring the production of recombinant human insulin. Combinations of these complementary techniques allowed us to obtain unambiguous information about the purity and primary structure of all intermediates of recombinant human insulin production, and they enabled the optimization of some process parameters. Figure 5.1-6 shows the result of a CZE analysis performed to check the purity of insulin purified by ion-exchange chromatography. This CZE analysis showed the presence of several impurities from the preparation (Arg-insulin) and degradation (unidentified desamido-insulins) in the isolated insulin.

SDS–CGE provides an overall composition of a protein sample based on the molecular mass, even if it is less suited for the analysis of subtle changes in a protein. Thus, SDS–CGE is mainly used to check for the presence of other proteins, protein aggregates, or protein degradation fragments in the purity checks.

Hunt and Nashabeh showed the SDS–CGE method with LIF detection for the analysis of humanized recombinant IgG_1-monoclonal antibody (MAb) [93]. For LIF detection, the MAb was first derivatized with a 5-carboxytetramethylrhoda-

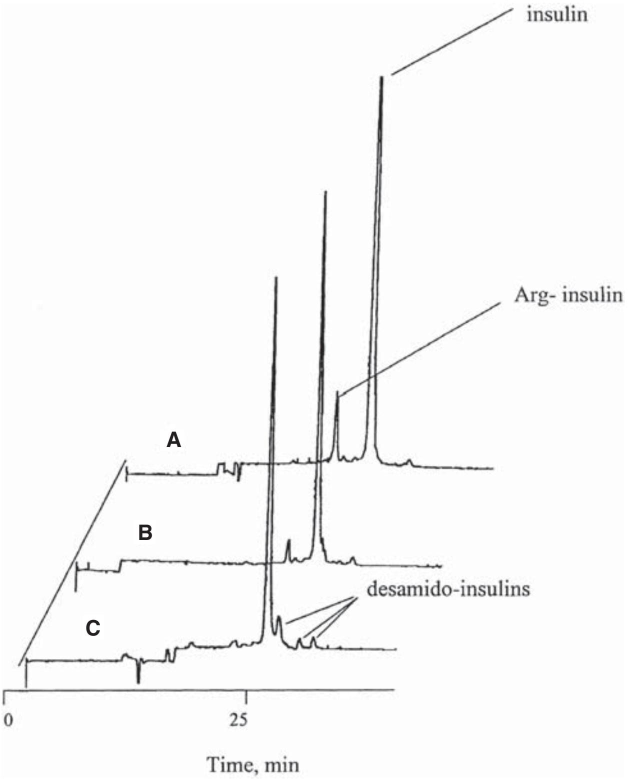

Figure 5.1-6. CZE analysis for insulin purity checks in three fractions obtained by ion-exchange chromatography. This CZE analysis demonstrated the presence of several impurities (Arg-insulin and desamido-insulins) in the isolated fractions. (Reprinted from Ref. 92, with permission.)

mine succinimidyl ester. The derivatized sample was then incubated with SDS, and the SDS–MAb complexes were separated by SDS–CGE using a hydrophilic polymer as a sieving matrix. The capabilities of SDS–CGE using UV detection or LIF detection after derivatization were compared. Figure 5.1-7 shows the results of the SDS–CGE analysis by UV detection at 220 nm and LIF detection using argon

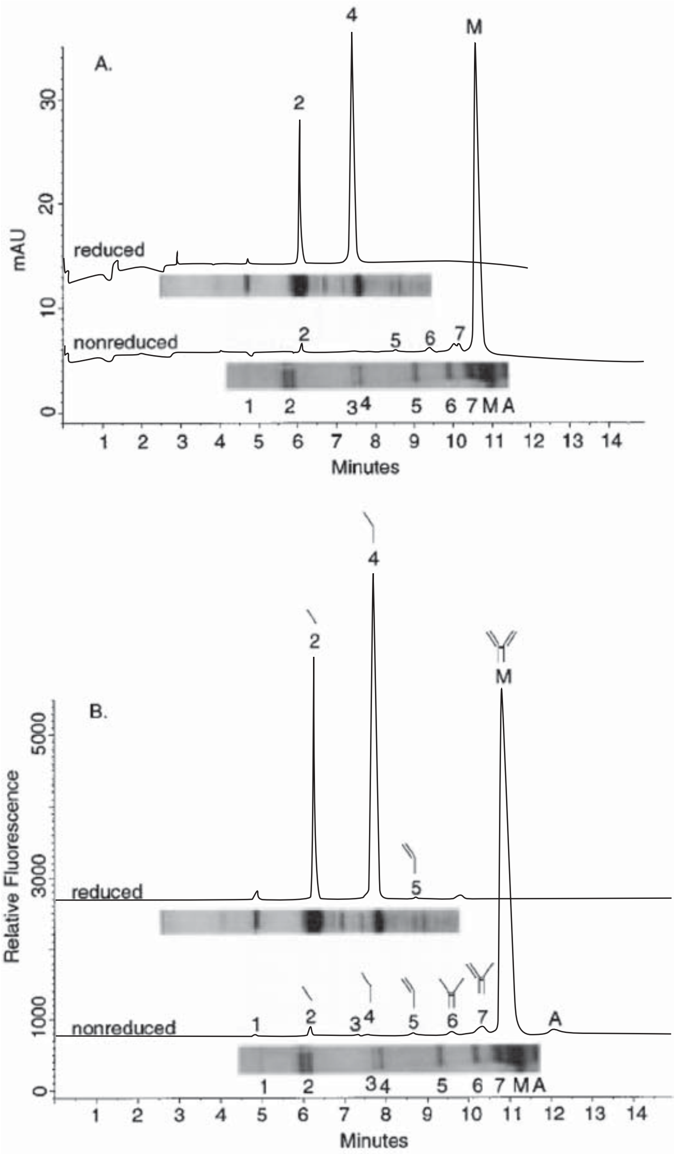

Figure 5.1-7. SDS–CGE separations of nonreduced and reduced preparations of a therapeutic recombinant MAb. Insets show silver-stained SDS–PAGE traces of the same sample preparations (M: monomer, A: aggregate). (A) UV detection of unlabeled samples at 220 nm. (B) LIF detection of labeled samples at 488-nm excitation and 560-nm emission. (Reprinted from Ref. 93, with permission.)

laser with excitation wavelength of 488 nm and emission wavelength of 560 nm. Under reducing conditions, the light and heavy chains originating from the original MAb were well separated, and the results of SDS–CGE under both reducing and nonreducing conditions generally showed good agreement with band profiles obtained by silver-stained SDS–PAGE. SDS–CGE using LIF detection allowed the detection of MAbs at a low-nanomolar concentration (~9 ng/mL), which was comparable with silver-stained SDS–PAGE and was a 140-fold increase over SDS–CGE using UV detection. This improved sensitivity also allowed the detection of low-level impurity peaks, which were not detected by UV detection. Repeated analysis showed that RSD values for the migration time were below 1%, and the RSD of the area of the main peak was lower than 0.6%. These applications demonstrate the usefulness of SDS–CGE–LIF for detecting manufacturing inconsistencies in recombinant protein production.

Several validated CZE and SDS–CGE methods for the purity analysis of peptides and proteins are provided in Table 5.1-2.

5.1.3.3 Heterogeneity Characterization of Glycoproteins

Glycoproteins produced from mammalian expression systems consist of a population of glycosylated variants (glycoforms). Glycosylation is one type of posttranslational modification that requires monitoring because variation in the carbohydrate composition may significantly alter the properties of a protein such as biological activity, pharmacokinetic properties, solubility, and stability. Several CE methods have been used for analyzing the intact glycoproteins and monitoring their production [3, 101]. Because of simplicity and high resolving capacity based on the charge-to-mass ratio, CZE has been routinely used for characterizing the heterogeneity of glycoproteins. In addition, CIEF has been increasingly used for separation of the glycoforms.

Erythropoietin (EPO). EPO is a glycoprotein produced primarily by the kidney and the main regulator of red blood cell production [102]. Human EPO consists of 165 amino acids that are heavily glycosylated (one O-linked and three N-linked carbohydrate chains corresponding to 40% of the molecular mass) [103]. Several glycoforms of human EPO exist with different degrees of glycosylation and sialic acid residue numbers [104]. Several reports are available on the application of CE for the separation of EPO glycoforms, involving different CE modes [105]. Among them, CZE and CIEF are the most successful CE modes in this respect. Table 5.1-3 provides an overview of the CE analyses of EPO glycoforms.

A CZE method for the characterization of the glycoform patterns of pharmaceutical EPO is included in the 2002 European Pharmacopoeia, as a substitute for the conventional isoelectric focusing test [113]. As shown in Figure 5.1-8, EPO was resolved with high resolution into its glycoforms using a separation buffer containing putrescine (1,4-diaminobutane) and urea [110]. Individual peaks correspond to multiple glycoforms with similar overall mass-to-charge ratios [3, 109, 114]. At pH 5.5, sialic acid residues are negatively charged and migrate against the EOF, and thus the glycoforms are considered to elute in the order of increasing number of sialic acid residues [109, 114]. The addition of putrescine to the separation buffer leads to a reduction in EOF and solute interaction with the capillary wall. Urea is

used to inhibit protein aggregation by preventing the formation of intermolecular hydrogen bonds and disrupting hydrophobic and noncovalent interactions [105]. Sanz-Nebot et al. described the CZE separation of a novel erythropoiesis-stimulating protein (NESP), which is a recently approved hyperglycosylated analog of human EPO with a long-lasting effect [110]. As NESP, due to its two extra *N*-linked oligosaccharide chains, has a higher sialic acid content than EPO, its glycoforms are expected to carry a higher overall negative charge at pH 5.5. As shown in Figure 5.1-8, NESP glycoforms migrated slower than EPO glycoforms at pH 5.5 and the peaks corresponding to NESP glycoforms were only partially resolved. Figure 5.1-9 shows the influence of separation buffer pH on the separation of NESP glycoforms. The peak resolution was improved at lower pH condition, which may be due to the

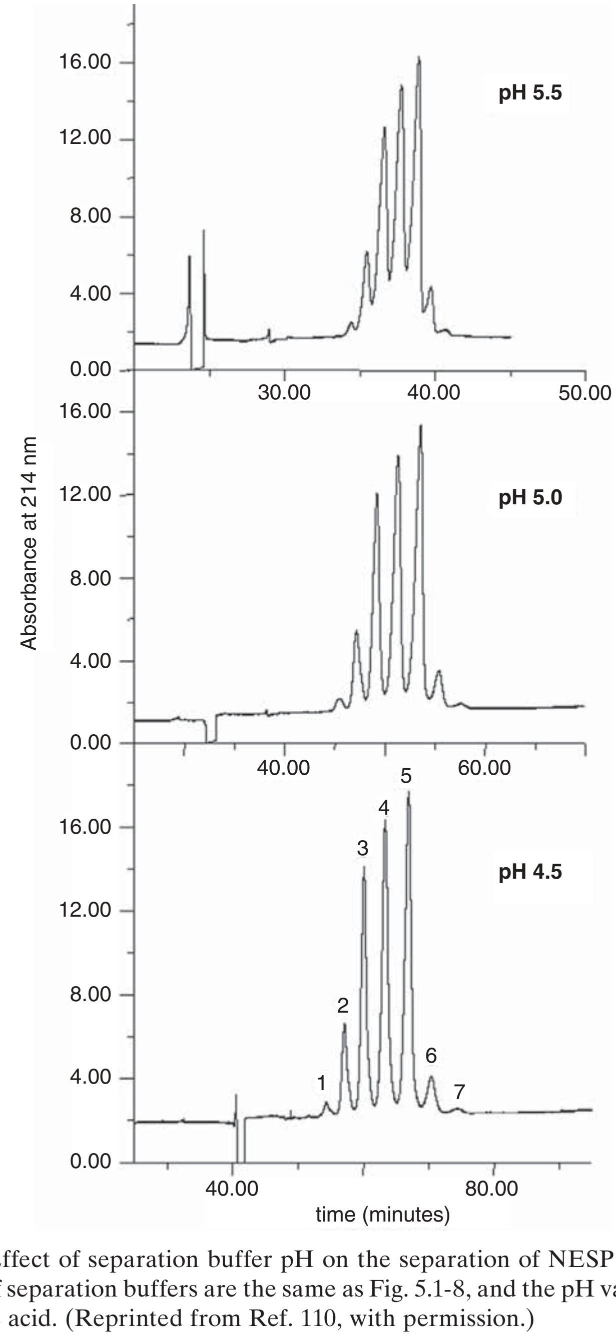

Figure 5.1-9. Effect of separation buffer pH on the separation of NESP glycoforms. The compositions of separation buffers are the same as Fig. 5.1-8, and the pH value was adjusted with 2-M acetic acid. (Reprinted from Ref. 110, with permission.)

lower p*I* of NESP compared with EPO. At pH 4.5, the seven peaks of NESP glycoforms were resolved to baseline.

CIEF is an important technique for analyzing the charged variants of EPO glycoforms on the basis of sialic acid content differences. Cifuentes et al. showed that EPO glycoforms could be resolved by using a mixture of broad and narrow

pH-range ampholytes and by adding urea to the EPO sample [111]. The separation and quantification of seven EPO glycoforms with apparent p*I* values of 3.78–4.69 was accomplished using an optimized hydrodynamic mobilization method. Compared with conventional gle-IEF, better resolution was obtained in a shorter time. Lopez-Soto-Yarritu et al. described an improved CIEF method for the separation of EPO glycoforms with neutral-coated capillaries using ampholytes in the pH range 2–10 and bovine β-lactoglobulin-A as an internal standard [112]. CIEF analysis of EPO glycoforms was achieved with a migration time reproducibility of 0.05% and peak area reproducibility better than 3.4%.

Monoclonal Antibodies. Monoclonal antibodies (MAbs) are being in-creasingly used for a variety of diagnostic and therapeutic applications. As is the case for most recombinant proteins, preparations of MAbs often show considerable heterogeneity due to posttranslational modifications involving glycosylation. CIEF has been widely used for the separation of charged isoforms of several MAbs [67, 115–117].

Hunt et al. reported validation of CIEF method for recombinant MAb C2B8 [115]. As shown in Figure 5.1-10, CIEF separated four isoforms of MAb C2B8. Among them, three peaks were identified as charge isoforms present due to incomplete C-terminal lysine processing and represent MAb C2B8 with 2 (peak 1), 1 (peak 2), and 0 (peak 3) C-terminal lysines, respectively. The CIEF method was validated in accordance with International Conference on Harmonization (ICH) guidelines, and the result demonstrated that it is accurate, precise, linear, and highly specific for the determination of identity and charge distribution of MAb C2B8.

Tang et al. performed a systematic study on the routine analysis of a recombinant immunoglobulin G (IgG) by CIEF [116]. The method used a dimethyl siloxane-coated capillary (DB-1) and a separation matrix of 2% ampholytes in 0.4%

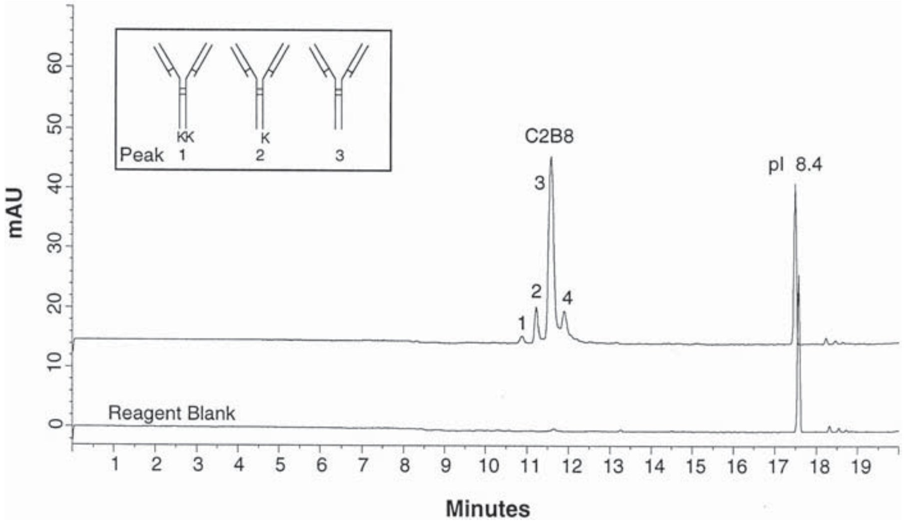

Figure 5.1-10. CIEF analysis of MAb C2B8. Box inset is a schematic illustration on the three C-terminal lysine variants. (Reprinted from Ref. 115, with permission.)

methylcellulose. The composition of various IgG samples with respect to isoform content was analyzed and compared quantitatively with gel-IEF. The reproducibility of the method was examined with the quantitative analysis of IgG sample in replicate over 3 days. The RSD of peak areas was below 2% intraday and 8% interday. The RSD for the mobilization times was below 1% intraday and 3% interday. Separation variability was examined over 150 runs. During this period, reproducible migration times and good resolution without peak shape deterioration were observed. This type of robustness demonstrates the potential of the CIEF method as a useful routine analysis tool.

Kats et al. employed the MEKC method to separate isoforms of chimeric MAb BR96 [118]. In the range from pH 2 to 12, MAb BR96 was separated into one to five isoforms by MEKC using a 12-mM borate buffer (pH 9.4) containing 25-mM SDS in uncoated capillary. Kats et al. further applied MEKC to separate structurally similar isoforms of a single-chain immunotoxin fusion protein BR96-sFV-PE40 using a 12-mM borate buffer (pH 9.6) containing 16-mM cholic acid [119].

Table 5.1-4 summarizes CE applications for the characterization of charge-based heterogeneity of several MAbs.

5.1.3.4 Stability Study

Peptides and proteins are complex molecules containing many functional groups, which can undergo a variety of degradation reactions, such as oxidation, reduction, deamidation, hydrolysis, arginine conversion, β-elimination, and racemization of amino acids [120]. Proteins further undergo physical changes in the secondary, tertiary, and quaternary structures [121]. These degradation reactions can alter the conformation, size, charge, and hydrophobicity of the peptides and proteins, thereby affecting the biological activity or even leading to formation of toxic compounds. As is recognized by the ICH guidelines for stability testing of biotechnological products, the monitoring of the stability of pharmaceutical peptides and proteins is of the utmost importance in the aspects of quality control and safety. CE has been used as a powerful tool for monitoring of stability and degradation of peptides and proteins in various conditions [122].

The high resolving power of CZE could be used for monitoring the stability and degradation reactions of peptide and protein products. Hoitink et al. applied CZE–MS for a stability study of goserelin, a luteinizing hormone-releasing hormone analog [123]. Using a 10% acetic acid as running buffer, high-resolution separation was obtained. In a stability study of goserelin at pH 5 and 9, the degradation of the C-terminal semi-carbazide group was observed. Lai et al. used CZE for the separation of asparagines-containing hexapeptide and its deamidation products and applied this method to a peptide stability study in the presence of polymers [124]. The offline CZE/MALDI–TOF MS combination has been used to monitor the stability of sCT, human parathyroid hormone 1-34 (PTH), and leuprolide in biodegradable PLGA microsphere formulations [64]. Figure 5.1-11 shows CZE monitoring of the sCT stability in the PLGA microspheres incubated in a 10-mM phosphate buffer saline (pH 7.4) containing 0.02% Tween 80 and 0.02% sodium azide at 37°C. CZE separations were performed using a 100-mM phosphate buffer (pH 2.5) in polyacylamide-coated capillary with UV detection at 200 nm. During the *in vitro* drug release study, intact sCT peak rapidly decreased, whereas the

additional peaks predominantly appeared after 28 days of incubation. MALDI–TOF MS data supported CE results with good correlation.

SDS–CGE can be also a useful stability-indicating method because it detects changes in fragmentation of proteins. Hunt et al. demonstrated that SDS–CGE could detect peaks resulting from the fragmention and aggregation of MAb HER2 when incubated at 37°C for 27 days [67]. Hunt and Nashabeh showed the potential of SDS-CGE for the separation and detection of proteolytic and deglycosylated fragments generated from MAbs [93].

5.1.3.5 Characterization of PEGylated Peptides and Proteins

The covalent attachment of PEG, PEGylation, is a well-established technique of overcoming several problems associated with the therapeutic uses of proteins. This technique has demonstrated reduced immunogenicity, extended circulating half-life, and improved stability for these therapeutic agents [125–127].

In general, the PEGylation process results in molecular heterogeneity with respect to the distribution in terms of number and positions of attached PEG molecules as well as the inherent polydispersity of PEG itself [128]. Therefore,

PEGylated molecules are among the most challenging products in analytical biochemistry, and their characterizations are becoming more important because these heterogeneities may confer different biological properties [129, 130]. When developing PEGylated biomolecules as therapeutic agents, various points should be considered, including the characterization of starting materials (i.e., proteins and PEG molecules), the determination of PEGylation sites, and the stoichiometry of PEG attachment [131]. The consistency of each preparation should also be established. For well-characterized PEGylated biomolecules, it is important to develop and validate suitable analytical techniques that enable consistent manufacturing processes to be established. Table 5.1-5 provides an overview of the applications of CE methods for the characterization of PEGylated peptides and proteins.

Cunico et al. described a charge-reversed CZE method for the analysis of PEGylated proteins [132]. A removable coating using ethylene glycol was applied to allow the negative capillary surface charge to be made positive, to prevent the protein adsorption to the capillary wall. Using this coated capillary, six different PEGylated molecules were characterized.

Bullock et al. characterized PEGylated superoxide dismutase (SOD) by CZE using a low-pH separation buffer (pH 2.05) [133]. At low pH, protein molecules are completely protonated and the charge differences between individual PEG-mers (i.e., mono-, di-, or tri-PEGmers) are minimized due to neutralization of lysine residues modified by PEG attachment. This results in a predominantly size-based separation of PEGylated proteins. Under low pH conditions, PEG–SOD conjugates were size-dependently separated and the separation pattern was very similar to the MALDI–TOF MS spectrum.

Li et al. used a semi-aqueous phosphate buffer (pH 2.5) of acetonitrile-water (1:1, v/v) to improve the resolution of PEGylated proteins [134]. They found that acetonitrile was mainly responsible for the good resolution observed, and this was attributed to reduced protein adsorption to the inner wall of the silica capillary used.

Na et al. determined PEGylation sites in three positional isomers of mono-PEGylated salmon calcitonins (mono-PEG-sCTs) using CZE-based peptide mapping analysis [135]. The resistance of PEGylation sites to proteolytic degradation resulted in different CE electropherogram patterns for tryptic digested mono-PEG–sCT isomers, and PEGylation sites were assigned accordingly and confirmed by MALDI–TOF MS.

Na and Lee reported on the characterization of PEGylated human parathyroid hormone (PEG–PTH) using CZE [136]. As shown in Figure 5.1-12, the CZE was used to optimize reaction conditions by monitoring the effects of reaction pH and the molar ratios of reactants on the PEGylation of PTH. The CZE method also allowed for determination of the extent of positional isomers in mono-PEG–PTH as well as for the identification of PEGylation sites.

Na et al. applied SDS–CGE to characterize PEGylated interferon alpha (PEG-IFN) [4]. The method well resolved the PEG–IFN species as well as the native IFN. As shown in Figure 5.1-13, four PEGylated IFNs (i.e., mono-, di-, tri-, and tetra-PEGylated IFNs) were detected and completely separated by SDS–CGE. The distribution of PEGylation reaction mixture in the SDS–CGE was found to be almost identical with that obtained by SDS–PAGE with Coomassie blue staining, although no band corresponding to tetra-PEGylated IFN was visualized.

TABLE 5.1-5. CE Applications for the Characterization of PEGylated Peptides and Proteins

Objective	CE Modes	Separation Buffers	Capillary	Detection	Ref.
Separation using charge-reversed mechanism	CZE	10-mM phosphate, 10% ethylene glycol (pH 2.0)	Uncoated	UV (215 nm)	[132]
Heterogeneity of PEG–SOD	CZE	15-mM boric acid, 15-mM 1,3-diaminopropane, 10-mM NaCl (pH 10.1)	Uncoated	UV (200 nm)	[137]
Separation of PEG–SOD and comparison with MALDI–TOF MS	CZE	40-mM phosphoric acid, 0.1-mg/mL PEG-114000, 4-mg/mL Jeffamine ED-600 (pH 2.05)	Uncoated	UV (200 nm)	[133]
Separation of PEG-lysozyme and peptide mapping	CZE	25-mM phosphate, 0.1-mg/mL PEG 600 K (pH 2.7)	Uncoated	UV (200 nm)	[138]
Separation of semi-aqueous CE method	CZE	25-mM sodium phosphate (pH 2.5), acetonitrile-water (1:1, v/v)	Uncoated	UV (200 nm)	[134]
Identification of PEGylation sites in mono-PEG-salmon calcitonin	CZE	100-mM sodium phosphate (pH 2.5)	Polyacrylamide-coated	UV (200 nm)	[135]
Identification of PEGylation sites in mono-PEG-human parathyroid hormone (1–34)	CZE	100-mM sodium phosphate (pH 2.5)	Polyacrylamide-coated	UV (200 nm)	[136]
Separation of PEG-interferon alpha	SDS–CGE	CE–SDS protein kit (Bio-Rad)	Uncoated	UV (220 nm)	[4]

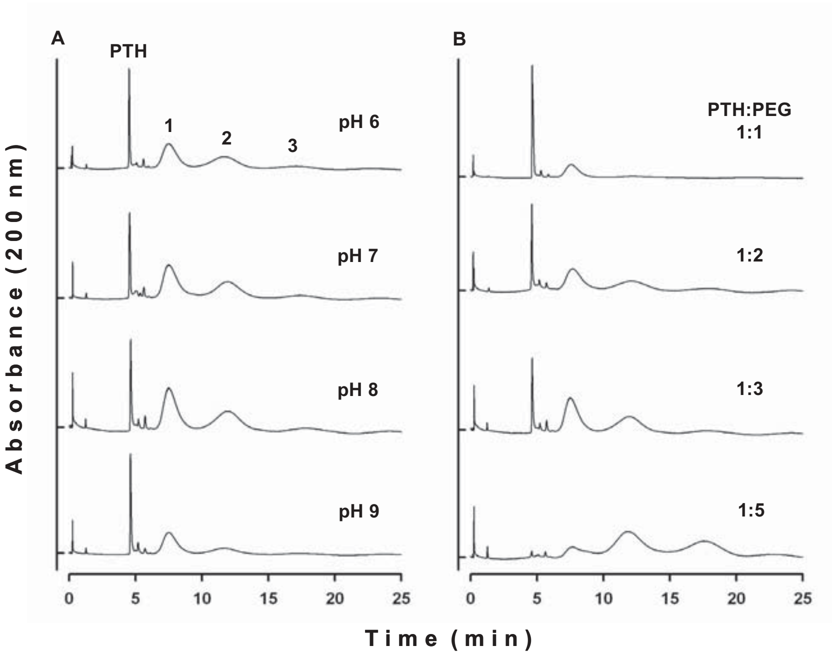

Figure 5.1-12. CZE monitoring of the PEGylation reaction of PTH through control of reaction pH (A) and molar ratios of reactants (B). The numbers above peaks represent the number of PEG molecules conjugated to PTH (i.e., 1: mono-, 2: di-, and 3: tri-PEGylated PTHs). (Reprinted from Ref. 136, with permission.)

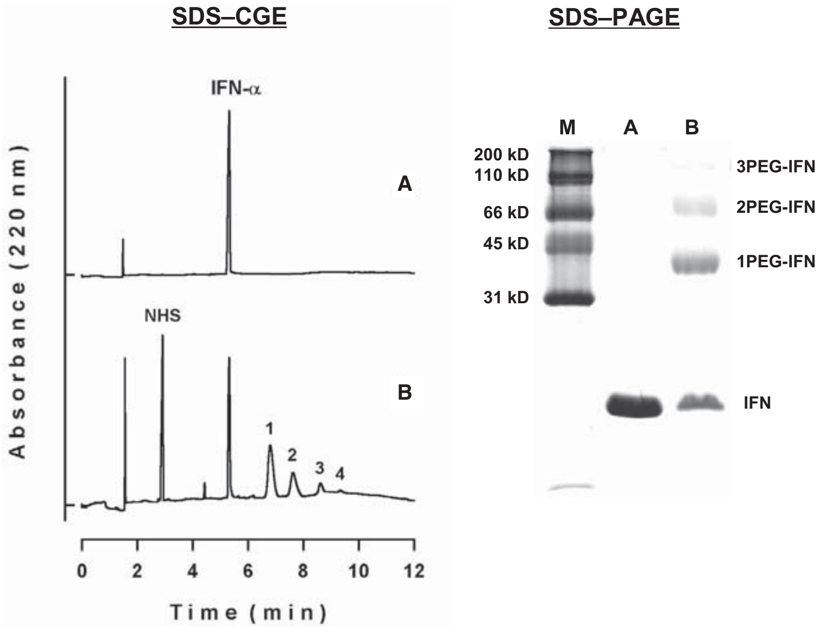

Figure 5.1-13. SDS–CGE and SDS–PAGE of IFNs before (A) and after (B) PEGylation reaction. In the SDS–CGE electropherogram, the numbers above the peaks represent the number of PEG molecules conjugated to IFN (i.e., 1: mono-, 2: di-, 3: tri-, and 4: tetra-PEGylated IFNs). (Reprinted from Ref. 4, with permission.) (This figure is available in full color at ftp://ftp.wiley.com/public/sci_ tech_med/pharmaceutical_biotech/.)

SDS–CGE was also useful for monitoring PEGylation reaction to optimize the reaction conditions such as the reaction molar ratio. This study demonstrated the potential of SDS–CGE for the characterization of PEGylated proteins with the advantages of speed, minimal sample consumption, and high resolution.

5.1.3.6 Proteome Analysis

Analysis of the proteome through the detection and identification of proteins from biological samples is gaining importance in the postgenomic era. The most traditional way to analyze proteome consists of protein separations by 2D gel electrophoresis (2-DE) and identifications by MS employing ESI or MALDI ionization [139]. However, the 2-DE–MS approach remains difficult for the detection of proteins expressed at extremely low levels or having extreme p*I* values or molecular masses and sensitivity [140]. In view of the limitations of 2-DE-based techniques, a considerable effort has been focused on the development of liquid phase-based analytical techniques, such as HPLC and CE, enabling the rapid, broad, and sensitive analysis of complex proteomic samples through the combination with MS or tandem MS analysis [5, 62, 141].

Various CE-based techniques have been widely used for proteome analysis, as has been described in numerous recent review articles [5, 62, 142, 143]. In addition to the complexity of protein samples, the large variation of the protein relative is one of the great challenges to the proteome analysis. For the broad proteome analysis, including the identification of lower abundance proteins, developments in capillary separations capable of providing extremely high resolving power and selective analyte enrichment are being highlighted [5]. As the resolving power of one-dimensional separation systems is generally not adequate for highly complex mixtures, multidimensional separations are becoming increasingly important for the comprehensive proteome analysis [7, 77].

Chen et al. developed an online combination system of CIEF with capillary RP–HPLC (CRPLC) using a microinjector as the interface for 2D separations of complex protein mixtures [144]. The resolving power of a combined CIEF–CRPLC system was demonstrated with tryptic digests of proteins from *Drosophila* salivary glands. The overall peak capacity was estimated to be around approximately 1800 over a run time of less than 8 hours.

Mohan and Lee developed a 2D CE separation system for proteomics by combining CIEF with transient capillary isotachophoresis (CITP)–CZE [145]. 2D separation of proteolytic peptides was applied to analyze tryptic digests of model proteins, including cytochrome c, ribonuclease A, and carbonic anhydrase II. Maximum peak capacity was estimated to be around 1600.

Ramsey et al. have combined MEKC with CZE, using switching of applied voltages to control fraction transport between the separation dimensions [146]. In analysis times of less than 15 min, 2D separation of tryptic digests of bovine serum albumin produced a peak capacity of 4200 (110 in the first dimension and 38 in the second dimension). The system was used to identify peptides from a tryptic digest of ovalbumin using standard addition and to distinguish between tryptic digests of human and bovine hemoglobin.

5.1.4 CONCLUSIONS

In biopharmaceutical analysis, CE is becoming the method of choice for the separation and characterization of peptide and protein pharmaceuticals. As shown in this chapter, the application of CE in this area has significantly increased during the past decade. The high efficient separation capability of CE provides an alternative and complementary technique to conventional analytical methods that are currently used to characterize biopharmaceuticals. Diverse separation modes of CE have been applied for the identity determination, purity control, heterogeneity characterization, stability study, and process consistency of biopharmaceuticals. In particular, CE has been recognized as a highly valuable tool for the efficient separation and characterization of the heterogeneous and complex protein products such as glycoproteins and PEGylated proteins. Recently, as the field of proteomics is becoming increasingly important, the role of CE in the strategy of protein analysis increases, with an emphasis on multidimensional separation and the combination of mass spectrometric techniques.

5.2.1 BIOASSAY FOR DETECTING TOXICITY OF TOXINS FROM A MICROORGANISM

Some *Fusarium* mycotoxins and the metabolites of filamentous fungi and molds occur naturally in a variety of feeds, foodstuffs, crops, vegetables, fruits, water, and plants. Ingestion of the contaminative feeds, foodstuffs, crops, vegetables, fruits, water, and plants can produce health problems, such as reduced growth, anorexia, induced emesis, enhanced proliferation of estrogen-responsive tumor cells, human cervical cancer, and premature initial breast development in humans and animals. Among the common toxins, verrucarin A, T2-toxin, roridin A, deoxynivalenol (DON), zearalenone (ZEN), fumonisin B1 (FB1), moniliformin (MON), microcystin-LR (MCLR), and the toxins from *Bacillus thuringiensis* provide a worldwide threat to humans and animals. Based on these facts that the lactose-utilizing yeast *Kluyveromyces marxianus* exhibits well-characterized β-galactosidase activity and has chromogenic substrates, the toxicants interfering with any cellular function required for induction and expression of β-galactosidase gene can suppress β-galactosidase activity, DON and fumonisin B can inhibit cell growth, the dehydrogenase ensurveyed enzymes involved in mitochondrial functions can be inhibited by the toxicants, in axenic culture the melanin precursor overproducer mutant strain of the ciliate *Tetrahymena thermophila* can be grown to high concentration, in protecting plants from the hazardous effects of xenobiotics glutathione S-transferase (GST) and glutathione peroxidase (GPX) can play essential roles, colorimetric yeast assay [1], ciliate *T. thermophila* assay [2], MTT assay [3], mortality and frass production assay [4], and *Lepidium sativum* assay [5] are established.

5.2.1.1 Colorimetric Yeast Assay for Detecting Trichothecene Mycotoxins

To 50 mL of liquid medium, a single-cell colony of *K. marxianus* GK1005 (maintained routinely and grown on 1% (w/v) yeast extract, 1% (w/v) bacteriological peptone, and 2% (w/v) glucose (YPD), solidified when required with 2% (w/v) agar) on agar plate is transfered to prepare cultures that are incubated for 16 h at 35°C and 200 rpm in a rotary incubator. At 560 nm, the absorbance is measured to determine cell density, which is calibrated by direct hemocytometer counts. Mycotoxins containing sample is dissolved in spectroscopic grade methanol to make stock solutions typically at 0.1 mg/mL. Cetyl trimethyl ammonium bromide, polymyxin B sulphate, and polymyxin B nonapeptide are dissolved in

water, filter-sterilized, and kept no more than a day as stock solutions. 5-Bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-gal) is dissolved in dimethylformamide (DMF) at 100 mg/mL and stored at −20°C in the dark, and before each assay, it is immediately diluted in aqueous DMF (2 parts water : 3 parts DMF) to prepare a working solution of 20-mg/mL X-gal assay. Before use *o*-nitrophenyl-β-D-galactopyranoside (ONPGal) is immediately dissolved in water at 4 mg/mL and subsequently discarded. Before use, MTT is dissolved in phosphate-buffered solution (PBS) and filter-sterilized to prepare a 5-mg/mL stock solution.

In the wells of a microtiter plate (sterile, flat-bottomed), 136 μL of growth medium consisted of 1% (w/v) yeast extract, 1% (w/v) bacteriological peptone, and 50-mM glucose—"YPD-50" are mixed with polymyxin B sulphate to give a final assay concentration of 15 μg/mL, to which 8 μL of stock solution of mycotoxin containing sample or methanol (controls) and 16 μL of yeast inoculum are successively added to give an initial assay cell density of approximately 2×10^8 cells/mL. Blank wells contain 152 μL of medium and 8 μL of methanol. The plate is mixed, sealed with a plate sealer, and incubated at 35°C for the duration of the assay, during which cell density is regularly monitored at 560 nm. After about 10 h, the control (mycotoxin-free) cultures reach the stationary phase; the activity of β-galactosidase or mitochondrial (MTT-cleavage) in the cultures is assayed.

To each well of the microtiter plate, 5 μL of sodium dodecyl sulfate (SDS) (0.1%, w/v) and 3 μL of chloroform are added to permeabilize the cells. For *in vivo* experiments and experiments examining the effects of different carbon sources, 1 μL of 100-mg/mL X-gal in DMF are added to each well. For examining the effects of altering glucose concentration and inoculum cell density, 5 μL of 20-mg/mL X-gal in DMF are added to each well. For methanol and ethanol toxicity experiments and the standardized bioassay, 8 μL of 20-mg/mL X-gal in aqueous DMF are added. After mixing the contents in the wells, the plates are incubated at 35°C for a maximum of 30 min. Using a test filter at 666 nm and a reference filter at 560 nm, the plates are read. β-Galactosidase activity is expressed as product formation (A_{666}–A_{560}), as a function of cell density (A_{560}) as well.

After the addition of 16 μL of MTT in PBS to each well and statically incubated at 35°C for 4 h, the medium is displaced by 200 μL of dimethyl sulfate (DMSO). Thorough mixing and dissolution the MTT-cleavage product is pipeted repeatedly. Using a test filter at 560 nm and a reference filter at 666 nm, the plates are read.

Into 50 mL of the solution consisting of 1% yeast extract, 1% bacteriological peptone, and 50-mM lactose, a single colony of *K. marxianus* GK1005 is inoculated and then incubated for 16 h at 35°C and 200 rpm in an orbital shaker. Into each of two universal bottles 10 mL of the samples of the culture are transferred, and then 0.2 mL of chloroform and 0.1 mL of SDS (0.1%, w/v) are added. To permeabilize the cells, to one bottle 20 μL of X-gal (100 mg/mL in DMF) are added, and to the other bottle 20 μL of DMF are added. In an orbital shaker, both bottles are incubated at 35°C and 200 rpm until in the bottle containing X-gal visible indigo precipitate is formed, of which the absorption spectrum is determined with DMF control sample as a reference.

5.2.1.2 Ciliate *T. thermophila* Assay for Detecting Trichothecene Mycotoxins

The phenotype characteristics of *T. thermophila* strain BI3840 are amicronucleated (amc), pigment producing (pig), and resistant to 25 μg/mL of cycloheximide (cy-r)

and mating type IV [6]. The PP210 medium consists of aqueous solution of proteose peptone (2%, w/v), supplemented with 10 µM of $FeCl_3$, 250 µg/mL of streptomycin sulphate, and penicillin G. Mycotoxins containing samples are dissolved in propyleneglycol or acetonitrile to make stock solutions at 5 mg/mL. *T. thermophila* strain BI3840 are grown axenically in PP210 medium for 24 h and maintained constantly at 28 ± 1°C. Then the exponential phase cellular suspensions are distributed in microtiter plates (100 µL/well). According to the required final concentration, different dilutions of the stock solutions of mycotoxins containing samples in PP210 medium are added into the cultures (100 µL/well). To each 100 µl/well of *T. thermophila* strain BI3840 culture, 100 µl/well of PP210 medium without a mycotoxin containing sample is added to obtain one type of control, and 100 µl/well of PP210 medium plus the highest concentration of the corresponding solvent added to obtain another type of control. In all cases, the microtiter plates are incubated at 28 ± 1°C for 48 h and the wells with a dark-brown pigmentation are considered as the positive growth wells.

5.2.1.3 MTT Assay for Detecting Fusarium Mycotoxins

Caco-2, C5-O, V79 cells (in Dulbecco's Modified Eagle Medium, DMEM), and Chinese hamster ovary (CHO)-K1 cells (in DMEM/F-12) at passage numbers between 30 and 50, and HepG2 cells (in Minimum Essential Medium) at passage numbers between 80 and 100, are grown as monolayers in 80-cm^2 culture flasks, which are harvested when they reach 80% confluence to maintain exponential growth.

Using trypsin ethylenediaminetetraacetic acid (EDTA) (0.25% trypsin and 1-mM EDTA·4Na), the cell monolayers in exponential growth are harvested and after repeated pipetting the single-cell suspensions are obtained. To 96 well plates, the single cell suspensions (1×10^2 to 5×10^4 cells per 200 µL medium/well) are added by serial dilution. The medium are supplemented with 1.5-g/L sodium bicarbonate, 0.11-g/L sodium pyruvate, 1% nonessential amino acid, 25-mM HEPES, 100 U of penicillin/mL, 100 µg of streptomycin/mL, 25 ng of amphotericin B/mL, and 10% fetal bovine serum). Caco-2, C5-O, HepG2 (1×10^4 cells/100-µL medium), CHO-K1, and V79 (5×10^3 cells/100-µL medium) are seeded to each well of the 96 well plates and incubated in a humidified atmosphere of 5% CO_2 at 37°C for 24 h. A mycotoxin containing sample in 100 µL of medium is added from high to low concentration to the wells and adjusted to final concentration needed. MTT is dissolved in PBS (5-mg/mL final concentration), filtered (0.22-µm filter), and stored in the amber vials at 4°C for a month. After 48-h and 72-h incubation, to each well, 25 µL of MTT solution is added and incubated in a humidified atmosphere of 5% CO_2 at 37°C for 4 h. At the end of the incubation period, the media are discarded using a suction pump. The extraction buffer of 20% (w/v) SDS in a solution of 50% DMF in demineralized water (50 : 50, v/v) is prepared at pH 4.7 and filtered (0.22-µm filter). The buffer in 100 µL of 20% (w/v) of SDS [7] is extracted and added into each well to solubilize formazan crystals, and the plates are shaked at 37°C overnight. The absorbance is measured at 570 nm with 690 nm as a reference wavelength. The positive control contains an adjusted seeding cell number in the log phase, of which the culture medium contains 0.1% ethanol.

5.2.1.4 Mortality and Frass Production Assay for Detecting Toxicity of Bacterial Strains

B. thuringiensis subsp. *tenebrionis* and the six unidentified strains of *B. thuringiensis,* labeled A30, A299, A311, A409, A410, and A429, are grown on nutrient agar buffered with an equimolar concentration of KH_2PO_4 (50 mM, pH 7.0) at 30°C for 5 days. The bacterial culture consists of vegetative cells, sporangia, spores, and crystals. These stages are lyophilized and stored at –20°C. The spore-crystal suspensions of each strain with 1:1 in the spore:crystal ratio are used in the toxicity assays [8]. The concentration of extractable proteins (the final protein solution is referred to as extractable protein) is determined and adjusted to a given concentration of protein in the crystal-spore mixture. Spore-crystal mixtures are suspended in Triton X-100 solution (0.01%, v/v) and washed three times by centrifugation at 22°C and 11750 g for 3 min. To extract the proteins, the final pellet in a putatively selective crystal solubilizing buffer (40.5-mM Na_2CO_3, 0.5-mM phenylmethylsulfonylfluoride, 0.1-mM dithiothreitol, pH 10.0) is solubilized at 42°C by incubating for 2 h and vortexing every 30 min [9]. The suspension is centrifuged (22°C, 11750 g, 3 min), and the supernatant is assayed for total protein with bovine serum albumin as the standard [10]. The laboratory cultures of plants are periodically supplemented with pest insects to maintain hybrid vigor. The colony is reared in an incubator at 24°C under the light for 16 h and at 16°C in the darkness for 8 h. Abundant food is placed in plastic petri dishes (100 mm in diameter) with moist filter paper that contains 10 adults, the plastic petri dishes are incubated, and the number of frass pellets on filter paper is counted daily for 3 days.

Adult mortality and modified frass production assays are used to measure the toxicity of the extractable proteins of the bacterial strains against plants [11]. The modified frass production assay is regarded as a rapid method to determine the specificity of numerous bacterial strains toxins against pest insect. The food cylinders (6 mm in length, 36 mm in diameter, 10 cylinders/plate) of optimum medium for insect feeding are cut from foliage homogenate supplemented with agar. The cylinders are dipped into distilled water containing different concentration of the extractable proteins, agitated for 5 s, air-dried, and then coated with test spore-crystal suspensions. The concentration of extractable proteins is 75-, 150-, 225-, and 300-μg protein/mL with distilled water as a control. Three to eight days after eclosion, starved adults are collected and added to the diet in petri dishes (15 × 100 mm diameter) containing moistened filter paper (15 adult insects per plate per dose). In the mortality assay, insects are fed at 25°C in darkness for 8 days. Mortality is monitored daily, and the LC_{50} for each test strain is calculated by probit analysis. In the frass assay, insects are fed for 6 days. The total number of frass pellets is calculated.

5.2.1.5 *L. sativum* Assay for Detecting Microcystin Toxicity

Toxic *Microcystis aeruginosa* PCC 7806 is cultured, and sufficient aeration is provided for culture mixing and air supply. From the freeze-dried cells, toxin is extracted by 70% aqueous methanol and determined using the protein phosphatase inhibition assay from the difference in the change in absorbance at 410 nm [12, 13]. With 5% H_2O_2 for 5 min, the seeds of *L. sativum* are surface sterilized, washed three times with sterile water for 10 min, left in fresh water overnight to germinate,

and then transferred to nutrient medium containing 6.5% N, 2.7% P, 13% K, 7% Ca, 2.2% Mg, 7.5% S, 0.15% Fe, 0.024% Mn, 0.0024% B, 0.005% Zn, 0.002% Cu, and 0.001% Mo in 0.8% agar. The container (12 seeds/container) is cultured at 27°C under continuous light (20 photons/m^2/s). Before pouring, either 1- or 10-μg/L microcystin-LR (MCLR) toxin extracts are added to the medium. The fresh weights, root, and leaf lengths are measured daily in 2 days. GST and GPX activities are determined in 3 days.

The stems and roots of 10 plants from each of three containers from each group are prepared for 30% homogenate of plant material in buffer (0.01-M Tris-HCl pH 7.8, 7.5-mM PMSF, 2.5-mM EDTA, 325-μM bestatin, 3.5-μM E-64, 2.5-μM leupeptin, and 0.75-μM aprotinin). The homogenate is centrifuged at 4°C and 12,000 g in a benchtop centrifuge for 2 h, and the supernatant is stored at −80°C for the GST and GPX assay.

In the GST assay, to the supernatant fluid, a cocktail containing 0.1-M potassium phosphate (pH 6.5), 30-mM 1-chloro-2,4-dinitrobenzene and 20-mM glutathione are added and measured immediately at 340 nm for 4 min [14]. In the GPX assay, to the supernatant fluid, a cocktail of 0.1-mM potassium phosphate buffer (pH 7), glutathione reductase (4 ng/μL final), 10-mM glutathione, 30-mM EDTA, and 1-mM NADPH is added. The reaction is initated by adding cumene hydroperoxide and measured immediately at 340 nm for 3 min.

5.2.2 TOXICITY BIOASSAY FOR CHEMICALS

Environmental chemical contaminants as toxic agents may be suspended in air, absorbed in suspended particulate matter (SPM) and foods, and dissolved in water, and thus, they may result in several toxic effects such as DNA damage, decline in lung function, imbalance of immune function, activation of aryl hydrocarbon receptor (AhR), abnormal reproduction, and urinary bladder injuries. Lux-Fluoro assay is developed on specific lesions for cells induced by DNA damaging chemicals may lead to cell death or induce an error-prone repair pathway leading to mutagenesis and cancer induction [15]. Based on the air-liquid interface culture (ALIC) of the human alveolar type II cell line (A459) and culture of spleen cells obtained from BALB/c mice producing IgM after pokeweed mitogen (PWM) stimulation, ALIC-based assay and PWM-induced IgM assay are established [16, 17]. Exposure to extremely low concentrations of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) results in activation of AhR and the induction of expression of a battery of genes, green fluorescent protein (GFP)-based cell assay is established [18]. In Reproductive Assessment by Continuous Breeding (RACB) protocol, differential follicle counts can provide a sensitive means of estimating the extent of ovarian toxicity in females exposed to xenobiotics [19]. Based on these facts that urinary bladder injuries induced by repeated oral administration of pharmaceuticals may be epithelial ulceration with edema and hemorrhage in the lamina propria and muscle layer of the urinary bladder, environmental chemical contaminants disrupt mammalian peptide signal transduction pathway via the interaction with the endocrine system in humans and various wildlife species and the cellular production of GFP is a function of nitrate concentration, uroepithelial cell assay [20], mating efficiency assay [21], and Pnar-gfp assay [22] are established and can be used in bioassays.

5.2.2.1 Lux-Fluoro Assay for Detecting Combined Genotoxicity and Cytotoxicity of Chemicals

The plasmid pPLS-1 (DSM10333), the genotoxicity sensing reporter component of the test panel, which carries the luxCDABFE genes downstream of a strong SOS-dependent promoter is constructed. The plasmid pGFPuv that carries the optimized "cycle 3" variant of GFP in frame with the lacZ initiation codon is the cytotoxicity sensing reporter component of the test panel. According to the modified "Hanahan" procedure, pPLS-1 and pGFPuv are used to transform the strain *S. typhimurium* TA1535 (ATCC: *S. choleraesuis* subsp. *choleraesuis* strain TA1535) [23]. For selecting plasmid carrying cells, the bacteria are cultured at 37°C in NB-medium supplemented with 50-µg/mL ampicillin. The DNA damaging agents containing sample are dissolved in distilled water at high concentration and diluted for the test. Each well of White LB96P-CMP Mikro Lumat Plates with a transparent bottom contains 10 µL of the solvent or different concentration of the test sample. The agar plate containing a single colony of bacteria, 10 mL of NB-medium with 50-µg/mL ampicillin, is shaken on a rotary shaker at 37°C for 16 h. Then the dilution (1:50) of bacteria in fresh warm NB-medium containing 50-µg/mL ampicillin are incubated at 37°C until the absorbance at 600 nm (A_{600}) reaches 0.2–0.3. Aliquots of 90 µL of this culture are added to each well, the microplate is covered with a gas-permeable self-adhesive seal and placed into the temperature-controlled microplate reader. The absorbance, luminescence, and fluorescence of the culture is successively and repeatedly determined by the programmed measurement cycle at 30°C for up to 8 h of continuous incubation with a duration of about 10 min per measurement cycle (total of 50 cycles). The measurement cycle of each well includes 120-s shaking, 0.2-s luminescence measurement without filter, 0.1-s absorbance measurement (490 nm, 20 nm bandwidth), and 0.1-s fluorescence measurement (excitation at 405 nm, emission at 510 nm).

5.2.2.2 ALIC-Based Assay for Detecting Toxicity of Chemicals in SPM

A549 cells and Hep G2 cells cultured in DMEM supplemented with 10% fetal bovine serum, 20-mM hydroxyethylpiperazine-N′-2-ethanesulfonic acid, penicillin (100 U/mL), streptomycin (100 µg/mL), amphotericin B (0.25 µg/mL), and 1.0% non-essential amino acid solution (only for Hep G2 cells) are subcultivated using 0.25% trypsin and 0.02% EDTA in PBS. After collection by trypsinization A549 cells are seeded at 1.0×10^5 cells/cm^2 onto the membrane culture insert precoated with a 0.03% type collagen solution. Initially, to both the apical (Ap) and the BL sides, the medium is added. Using a phase contrast microscope, the formation of the cell sheet is assessed. The evaluation of the development of tight junctions in the cell layers with a Millicell-ERS is performed based on the measurement of trans-epithelium electrical resistance (TEER). Until the TEER shows constant and saturated values (45–50 Ωcm^2 without the blank value of the membrane itself), the culture medium of A549 cells in the Ap side is removed and the ALIC is started. The chemical-free SPM samples are sterilized by ethylene oxide gas (EOG) performed with a commercially available sterilization system. After being measured carefully with a digital weighting machine, the EOG-sterilized SPM samples are loaded directly to the Ap side of an A549 cell layer in ALIC. In 12 well plates, A549 and Hep G2 cells are seeded at 1.0×10^5 cells/cm^2, cultured, and used after

they reach confluence. In the preparation of the extracts of the SPM samples, the suspension of 24 mg of each sample and 200 µL of DMSO is sonicated for 15 min and centrifuged for 10 min at 15,000 rpm, and the supernatant is diluted with culture medium to adjust the final concentration of DMSO in the culture medium 0.5% and the highest concentration of SPM in the culture medium 600-µg-SPM/mL-culture medium, which corresponds to the cell-surface-area-based load of the 158-µg-SPM/cm^2-cell surface.

The suspension of an SPM sample in 100 mL of CH_2Cl_2 is sonicated for 15 min and filtered with a membrane that has a 0.1-µm pore size, the filtrate is evaporated, and the residue is resolved in acetonitrile [24]. The concentration of the chemicals in the SPM extracts is determined using a multicolumn high-performance liquid chromatography (HPLC)/spectrofluorometer/computer system. According to $EQ = S([PAH]_1EF_1 + \ldots + [PAH]_nEF_n)$, the chemically derived induction equivalent (EQ) is calculated to standardize the biological effect of the chemical on the EROD capacity of the Hep G2 cells [25].

After 48 h of exposure of SPM, each culture is rinsed twice with PBS, and to the Ap and BL sides, 500 µL and 1.5 mL of the substrate solution of acid phosphatase is added, respectively. For the monolayer culture, 1 mL of AP solution is added, the 12 well plates are incubated at 37°C for 2 h, the absorbance is measured at 405 nm with the value of cell-free well as control, and the cell survivability is calculated by referencing a predetermined calibration curve.

A549 and Hep G2 cells are cultured in 12 well plates, washed twice with PBS, and loaded with 10-µM 7-ethoxyresorufin in the presence of 10-µM dicumarol in culture medium. After 1 h of incubation, the fluorescence intensity is measured (530-nm excitation wavelength, 585-nm emission wavelength) to detect the formed resorufin. The intensity is calibrated to the resorufin concentration using a standard curve.

5.2.2.3 PWM-Induced IgM Assay for Detecting the Toxicity of Chemicals

The toxicants containing sample are dissolved in Ca, Mg-free PBS or DMSO, or the vehicle solvent (10 µL each). Spleen cells are aseptically removed from BALB/cAnN mice (8–9 weeks old) [26], washed in Hanks' balanced salt solution supplemented with 10-mM HEPES buffer (pH 7.4), and diluted by RPMI 1640 medium containing 10% heat-inactivated fetal bovine serum, 2-mM glutamine, 0.4-M sodium pyruvate, 20-mM mercaptoethanol, non-essential amino acids, and antibiotics to prepare suspensions of 10^6 cells/mL. Cells are cultivated in a 24-well culture plate under 5% CO_2-air and the presence of PWM at 37°C for 2 to 6 days, supplemented with chemical toxicants containing a sample at the beginning of the culture. A total of 700 µL of culture media and residual cells in 300 µL of media are used for total IgM assay and cell proliferation assay, respectively.

The 96-well microtiter immunoplates are precoated overnight at 4°C with 100 µL of rabbit anti-mouse IgM antibody (IgG) in PBS (pH 7.4), washed with PBS containing 0.05% Tween20, and blocked overnight at 4°C with 150 µL of PBS containing 1% BSA. Each well is washed with PBS; into each well, 100-µL aliquots of culture media mentioned above (usually 11-fold diluted media) or reference mouse serum or standard mouse IgM diluted with 1% BSA-PBS are added, left at room temperature for 60 min, washed, and incubated; and 100-µL aliquots of horseraddish peroxidase-conjugated goat antimouse IgG in PBS are added. Sixty minutes

later, to each well, 150-μL aliquots of substrate solutions containing 0.4% o-phenylenediamine and 0.01% hydrogen peroxide in 0.1-M citrate–0.2-M phosphate buffer are added and incubated. Fifteen minutes later, 50 μl of H_2SO_4 (0.5 M) is added to terminate the enzyme reaction. Using a microplate reader the optical density at 490 nm of each well is read.

After the addition of 30 μL of TetraColar One reagent, 300 μL of media mentioned above are incubated under 5% CO_2-air at 37°C for 2 h. The optical density at 450 nm of the media containing the water-soluble tetrazolium salt produced by the enzyme reaction is read, and the cell number in cultures is measured by the modification (WST-8 method) of the MTT assay for mitochondrial dehydrogenase activity in viable cells [27].

5.2.2.4 GFP-Based Cell Assay for Detecting the Toxicity of TCDD and Related Chemicals

By excising the 1846 base-pair (bp) Hind III fragment from the plasmid pGudLuc1.1, pGreen1.1 is created [28]. pGreen1.1 contains the 480-bp dioxin-responsive domain from the mouse CYP1A1 gene inserted upstream of the mouse mammary tumor virus (MMTV) promoter, confers dioxin responsiveness upon the MMTV promoter and adjacent reporter gene, and is inserted into the Hind III site immediately upstream of the enhanced GFP reporter gene in the plasmid pEGFP-1.

Plates of the mouse hepatoma (Hepa1c1c7, approximately 80% confluent) cells maintained in αMEM containing 10% fetal bovine serum are transfected with the construct pGreen1.1 (20 μg) using polybrene, grown for 24 h, split 1 to 10, and replated into selective media. After growth for 4 weeks, resistant clones are isolated and screened for the EGFP assay. H1G1.1c3 cells and DMSO (1% maximum final concentration) or TCDD (1 nM in DMSO) are cultured in 6-well culture plates at 37°C for 24 h, harvested by scraping into lysis buffer (50-mM NaH_2PO_4, 10-mM Tris-HCl pH 8, 200-mM NaCl), and lysed by repeated passage through a 27-gauge needle. The medium is centrifuged, and the fluorescence of an aliquot of the supernatant is determined (460-nm excitation wavelength, 510-nm emission wavelength). In the microtiter plate analysis of EGFP, the intact cells are plated into 96-well tissue culture dishes at 7.5×10^4 cells/well and allowed to attach for 24 h. The selective media are then changed to 100 μL of nonselective media containing the test chemical or DMSO (1% final solvent concentration). EGFP levels of the intact cells in the nonselective media are measured (at the indicated time points, 485-nm excitation wavelength, 515-nm emission wavelength). To normalize results between experiments, the instrument fluorescence gain setting is adjusted so that the level of EGFP induction by 1-nM TCDD produces a relative fluorescence of 9000 relative fluorescence units (RFUs). To photograph the cells, after growth on 25-mm round cover slips for 24 h and treated with DMSO or a 1-nM TCDD containing sample for 48 h, H1G1.1c3 cells are replaced into PBS. Cell fluorescence is visualized at a 490-nm excitation filter and 535-nm emission filter.

Recombinant mouse hepatoma (H1L1.1c2) cells grown in 24-well microplates are incubated with DMSO (10 μL/mL) and a TCDD containing sample in DMSO or its related chemical containing sample in DMSO at 37°C for 4 h; luciferase activity of cells in each well is determined and normalized to sample protein concentration using fluorescamine with bovine serum albumin as the standard [29, 30].

The complementary pair of 5′-GAT-CTG-GCTCTTCTCACGCAACTCCG-3′ and 5′-GATCCGGAGTTGCGTGAGAAGAGCCA-3′ (corr-esponding to the AhR binding site of DRE3 and designated as the DRE oligonucleotide) is radio-labeled with [γ^{12}P]ATP (6000 Ci/mmol). Gel retardation analysis of cytosolic AhR complexes transformed *in vitro* with a TCDD containing sample (20 nM) or related chemical containing sample is performed and protein–DNA complexes are visualized. The amount of [^{32}P]-labeled DRE in the induced protein–DNA complex is determined.

5.2.2.5 RACB Protocol for Detecting Ovarian Toxicity of Xenobiotics

RACB protocol consists of Task 1 (initial dose-setting study), Task 2 (continuous breeding phase), Task 3 (crossover mating trial), and Task 4 (F_1 offspring dose). In Task 2, control (n = 40 animals/sex) and up to three treatment groups (n = 20 animals/sex) are implicated. In Task 2, F_0 (parental) rodents are exposed to a chemical containing sample during a 7-day premating period, randomly assigned to a mating pair, and treated with the same chemical containing sample and dose throughout a 98-day period of continual cohabitation (during which multiple litters are born). To encourage immediate remating, in early pregnancies, neonates are removed from the dam within 12 h. The principal toxicity in Task 2 is aberrant reproductive performance in F_0 rodents as indicated by alterations in the number of litters per breeding pair or neonatal body weight and sex ratio. If a positive toxicity is observed in Task 2, Task 3 should be performed to determine whether males or females are more sensitive. For this phase, both male and female high-dose F_0 mice are paired to control F_0 mice of the opposite sex, and reproductive performance is compared to determine the affected sex (es). If a negative toxicity is observed in Task 2, Task 3 is omitted. After 98 days, breeding pairs are separated and continuously treated until the F_1 generation is delivered and weaned. In Task 4 the F_1 offspring of Task 2 parents are dosed until 74 ± 10 days of age, at which time male and female animals from the same treatment group but different litters are mated (n = 20 /sex/group) to generate F_2 litters. The F_1 offspring have been exposed to the chemical as gametes and as young adults during prenatal and postnatal development.

Ovaries from Task 1 (approximately 50 days old), F_0 parents from negative Task 2 (approximately 215 days old) or from Task 3 (approximately 240 days old), or F_1 offspring from Task 4 (approximately 120 days old) are removed at necropsy, trimmed of fat, fixed by immersion in Bouin's solution for 12 to 24 h, and transferred to 70% ethanol for storage and transport. An intact ovary from each animal is dehydrated in graded alcohols and xylene, embedded in a longitudinal orientation in separate paraffin blocks, and sectioned serially at 6 µm (approximately 400 sections per ovary). To each slide (approximately 40 slides per ovary), two rows of five sections retained in sequence are applied and stained with hematoxylin and eosin. Counts of ovaries from 10 mice per group are gathered. Ovaries are available from only 5 to 6 treated animals in F_1 offspring from two Task 4 EGME assays and from 9 treated animals from Task 2 oxalic acid study. To produce an equal number of control tissues for analysis from untreated animals of the same studies, the ovaries are also chosen randomly. Beginning with the first section of the first slide, sections from each ovary are examined. At least from the third or fourth section

(a distance of 18 to 24 μm into the ovary), follicles are encountered and then categorized and enumerated. Differential counts from every tenth section or approximately 40 sections per ovary are made.

The ovarian follicles are categorized to small, growing, and antral ones by (1) the relative cross-sectional diameter of the follicle as measured from the outer margins of the granulosa cell layers, (2) the number of granulosa cell layers, and (3) the nature of the antral space. Small follicles, approximately 20 μm in mean diameters, consist of an isolated oocyte or an oocyte surrounded by a partial or unbroken, single layer of granulosa cells. Growing follicles, 20 to 70 μm, have an oocyte surrounded by a multilayered, solid mantle of granulosa cells. Antral follicles, more than 70 μm, are characterized by a central oocyte and fluid-filled space bordered by hundreds of layered granulosa cells [31]. Each counting session is limited to no more than 3 h to limit fatigue.

5.2.2.6 Uroepithelial Cell Assay for Detecting Urotoxicity of Chemicals

Male beagle dogs (31 months old) are individually housed at 23 ± 2°C and a relative humidity of 60 ± 20% with a 12-h light/dark cycle. The dogs from a control group are anesthetized by sodium pentobarbital (25 mg/kg, i.v.) and killed by exsanguination. The bladder is aseptically excised, then lengthwise incised, and washed three times with the Krebs solution containing 110-mM NaCl, 5.8-mM KCl, 25-mM $NaHCO_3$, 1.2-mM KH_2PO_4, 2.0-mM $CaCl_2$, 1.2-mM $MgSO_4$, and 11.1-mM glucose (pH 7.4) at 4°C. After removal of excess fatty tissues, the bladder is transferred, mucosal side down, to a metal rack with 10 sharp metal pins along each edge [32], placed in 4°C Krebs solution, and the smooth muscle layer is carefully removed. The tissue is stretched, mucosal side up, across the metal pins on a $10 \times 10/cm^2$ plate, incubated in the minimum essential medium (MEM) containing 1% (v/v) penicillin/streptomycin/fungizon (PSF), 2.5-mg/mL dispase, and 20-mM MEM/PSF/dispase solution (pH 7.4) at 4°C for 24 h, the MEM/PSF/dispase solution is aspirated, the stripped mucosa is transferred to a sterile 150-mm culture dish, and uroepithelial cells are scraped from the connective tissues with cell scrapers, which are suspended in 20 mL of trypsin-EDTA (0.25% trypsin and 1-mM EDTA·4Na) and incubated at 37°C for 30 min. Later, the single cell suspension is diluted with MEM containing 1% PSF, 5% FBS, and 20-mM MEM/PSF/FBS solution (pH 7.4) to 50 mL, spun down at 4°C, and centrifuged (1000 g, 5 min). The supernatant is aspirated to prepare the suspension of the cells in 50 mL of MEM/PSF/FBS solution. The cells are then rewashed in 50 mL of the keratinocyte-SFM medium and resuspended at $6.0–7.0 \times 10^5$ cells/mL.

By mixing 5 mg of type IV collagen, 100 μL of glacial acetic acid, and 50 mL of distilled water, the collagen solution is prepared, kept overnight at 4°C, sterilized with a 0.22-μm bottle top filter, and stored at 4°C. The keratinocyte medium is added to both chambers and incubated at 37°C for 2 h. Before use, the collagen solution is diluted 1:9 with 10-mM Na_2CO_3-HCl (pH 9.0), of which 500 μL is added to each apical chamber after aspirating the keratinocyte medium and incubated at 37°C for 1 h. Before plating, the collagen solution is aspirated, 0.5 mL of the cell suspension is added to the apical chamber, and 1.5 mL of keratinocyte medium is added to the basal chamber. After incubation at 37°C for 3 days, when the transepithelial electric resistance (TER) reaches levels of approximately $1000\,\Omega cm^2$ or

higher, the apical and basal media are aspirated and replaced with 0.5 and 1.5 mL of the keratinocyte medium containing 1-mM $CaCl_2$ (KM/Ca solution), respectively, and TER is measured. Before use, by immersing in 70% ethanol, the electrodes are sterilized and washed with sterile PBS, and Ωcm^2 are calculated.

Cultured cells on a 12-mm transwell filter are fixed in 2% glutaraldehyde of 0.1-M phosphate buffer (pH 7.4), rinsed with 8.2% sucrose, postfixed in 1% OsO_4 of the buffer, dehydrated with alcohol, and embedded in epoxy resin. For light microscopic examination, the semi-thin sections are stained with 1% toluidine blue. To observe cells with a transmission electron microscope, ultrathin sections are stained with uranyl acetate and lead citrate. For immunofluorescence staining, the cultured cells on a 12-mm transwell filter are successively fixed with HISTOCHOICE at room temperature for 1 min and acidic methanol (95% methanol and 5% glacial acetic acid) at −20°C for 15 min, then incubated successively with anti-ZO-1 rabbit polyclonal antibody diluted 1:50 with PBS for 1 h and FITC-conjugated donkey antirabbit IgG diluted 1:40 with PBS for 30 min, or incubated successively with anti-E-cadherin mouse monoclonal antibody 1:100 with PBS and FITC-conjugated goat antimouse IgG diluted 1:10 with PBS. To observe cells with a confocal laser scanning microscope, the cells are washed three times for 5 min with PBS, the cell-grown transwell filters are cut, transferred to a slide glass, and mounted with the mounting medium.

After plating on a 12-mm transwell filter, TERs are monitored for 20 days, during which the medium is replaced every 3 days. When TER reaches 10,000 Ωcm^2 or more, the cultured cells are observed and their ZO-1 and E-cadherin are checked. Validating this culture system in the examination of the effects of cytochalasin-B on TER and ZO-1, cytochalasin-B is first dissolved in DMSO, diluted with the KM/Ca solution to make concentration of 1.6 μM (final DMSO concentration, 0.08%), 4 μM (final DMSO concentration, 0.2%), and 10 μM (final DMSO concentration, 0.5%), and sterilized with a 0.22-μm membrane filter. TER is measured 0, 1, 2, 4, 8, 24, and 48 h after exposure, and immunofluorescence for ZO-1 is observed 48 h after exposure, with DMSO diluted 1:200 with KM/Ca solution serving as a negative control solution.

5.2.2.7 Mating Efficiency Assay for Detecting Toxicity of Endocrine Disruptors

In the pheromone signaling pathway experiment, yeast *Saccharomyces* cerevisiae strains W303A (MATa; ade2, his3, trp1, ura3) with pSL307 plasmid fused to the FUS1-lacZ are cultured in SD medium (0.67% yeast nitrogen base and 2% glucose/L) supplemented with adenine, l-histidine, and l-tryptophan at 30°C overnight. To fresh YPD medium (10 g of Bacto-yeast extract, 20 g of Bacto-peptone/L, and 2% glucose) or SD medium one tenth of the overnight culture is transferred, incubated at 30°C for 3 h, and the cultures that are adjusted at the logarithmic phase (OD = 0.8–1.0) of growth are harvested and subsequently used at 30°C [33].

W303A and W303A with fused plasmid pSL307 are incubated in YPD or SD medium for 60 min with or without test compound, harvested, washed three times with distilled water, and incubated in fresh YPD or SD medium with 5-mM α factor for 120 min to observe shmoo formation. Using a β-galactosidase activity assay, the pheromone response pathway in the W303A strain with pSL307 fused to the

FUS1-lacZ reporter gene is quantified [34]. Yeast cells are centrifuged at 3000 g, pellets are washed twice in distilled water, resuspended in 1.0 mL of Z buffer (21.5-g $Na_2HPO_4 \cdot 12H_2O$, 6.2-g $NaH_2PO_4 \cdot 2H_2O$, 0.75-g KCl, 0.246-g $MgSO_4 \cdot 7H_2O$, 2.7-mL β-mercaptoethanol/l, pH 7.0) with glass beads, with which three drops of chloroform and two drops of 0.1% SDS are mixed by ortex mixing, and incubated at 28°C for 5 min. After the addition of 0.2 mL of 4-mg/mL *p*-nitrophenyl-β-D-galactopyranoside at 28°C, the reaction is started, and by the addition of 0.5 mL of 1-M Na_2CO_3, the reaction is stopped. On removal of the cells by centrifugation, the superant is measured at 420 nm. In the mating efficiency assay, the diluted W303A strain is treated with the solution of test chemicals in YPD medium for 60 min and spread on both SD and YPD media. The colony-forming units (CFUs) of W303A strain on YPD medium are incubated for 2–3 days to give the cardinal number of mating efficiency. Simultaneously, the 144-3A strain (MATa; ura3, leu2, his4) is incubated on YPD medium for 60 min and streaked with diluted W303A strain on SD medium. Conjugated diploid 144-3A strain/W303A strain on SD medium complements the auxotrophy of each haploid cell.

5.2.2.8 Pnar-gfp Assay for Detecting Carcinogenic Toxicity of Nitrate

Escherichia coli DH5α (Φ80dlacZΔM15 recA endA gyrA thi hsdR supE relA deoRΔ [lacZYA-argF]), pUC18 (for routine cloning procedures), pCRII (for TA cloning of PCR products), pGreen-TIR containing the gfp gene, and pMV4 containing the narG promoter are used [35, 36]. Minimal medium (pH 7.0) contains 3.9-mM KH_2PO_4, 6.1-mM K_2HPO_4, 1.5-mM $(NH_4)_2SO_4$, 0.2-mM $MgSO_4 \cdot 7H_2O$, 22.4-μM $MnSO_4 \cdot 4H_2O$, 0.9-μM $FeSO_4 \cdot 4H_2O$, 4.4-μM $CaCl_2 \cdot 2H_2O$, 400-mg/L casamino acids, 14.8-μM thiamine hydrochloride, and 22.2-mM glucose. LB medium (pH 7.5) contains 10-g/L bacto-tryptone, 5-g/L yeast extract, and 10-g/L NaCl. *E. coli* DH5α (pPNARGFP) cultures are supplemented with 100-μg/mL ampicillin. Primers J1 (5′-CATCGAATTCTCCTGTGGGAGCCT-3′) and J2 (5′-CTGGCATGCATTCACTTGCCGCCTT-3′) are designated for the amplification of the nar promoter [37, 38]. J1 contains an artificial GAATTC (EcoRI site) and anneals to nucleotides +3 to −23 in the nar region, where +1 is the first nucleotide of the start codon. J2 contains an artificial GCATGC (SphI site) and anneals to nucleotides −438 to −414. After purification using Qiagen Plasmid Midi Kits (Qiagen, USA) or Wizard Plus SV miniprep kits (Promega, USA), the DNA sequence is determined by MWG Biotech (Milton Keynes, UK). The whole bacterial cells are measured with an excitation wavelength of 480 nm (10-nm bandwidth) and an emission wavelength of 510 nm (5-nm bandwidth) on a fluorescence spectrometer. The nitrate-induced fluorescence image of *E. coli* DH5α (pPNARGFP) is obtained with a BP465-495 excitation filter and a Ba 520 emission filter on a fluorescence microscope equipped with epifluorescence optics. The measurements of optical density are performed on a spectrophotometer at 600 nm.

5.2.3 ANTIVIRAL AND ANTICANCER ASSAY

The elucidation of the mechanisms of special enzymes provides the bases for highly specific and sensitive bioassays focused on the target enzymes and cells. The

alkaline phosphatase (AP) enzyme in the human endometrial adenocarcinoma cell line is sensitive to estrogen stimulation. Selective inhibition of the lyase activity of DNA polymerase sensitizes cancer cells to DNA-damaging agents. The human immunodeficiency virus type-1 reverse transcriptase (HIV-1 RT) and protease play key roles in HIV replication. The overexpression of the P-glycoprotein can produce cancer cell multidrug resistance (MDR). The receptor phosphorylation may induce ligand-induced receptor tyrosine kinase activation. Based on these facts, the human breast cancer cell assay [39], the Ishikawa cell and rat assay [40], the RT–PCR and swine assay [41], the antitubercular and cytotoxic assay [42], the DNA polymerase β lyase assay [43], the HIV-1 protease and reverse transcriptase kinetic assay [44], the P-glycoprotein pump assay [45], and the kinase receptor activation (KIRA) assay [46] are established and can be used in bioassays.

5.2.3.1 Human Breast Cancer Cell Assay for Detecting Anticancer Activity

Toxicity against brine shrimp *Artemia salina* nauplii is carried out in 96-well microplates using emetine hydrochloride as a positive control [47]. The selection of human breast cancer cell lines (MCF-7, MCF-7/ADR, MT-1, and MDA-MB-435) provides cells with a variety of receptor types; for instance, MCF-7 cells express high levels of estrogen receptors, MCF-7/ADR cells are resistant to doxorubicin, MT-1 cells have low estrogen receptor levels [48], the MDA-MB435 cell line has no estrogen receptors. In the determination of inhibition of cell growth in 96-well microtitre plates, the MTT assay is used [49]. The samples of test compounds in DMSO are diluted in medium so that the concentration of DMSO is more than 1% and does not affect cell growth. Overall, 180-μL aliquots of a cell suspension (1–2 $\times 10^4$ cells/mL) are plated into microplate wells and incubated overnight at 37°C in air containing 5% CO_2, and 150 μL of the culture medium is replaced with 150 μL of fresh medium, to which 20 μL of the solution of the test sample in medium is added to give final concentrations in the plate of 10, 1, 0.1, 0.01, and 0.001 μg/mL. Control wells with medium only and a positive control with 5-fluorouracil are used in each test. After 96 h of the incubation, 150 μL of medium is replaced with 150 μL of fresh medium, to which 20 μL of the 5-mg/mL MTT solution is added. After incubation for 4 h, 180 μL of medium is replaced with 180 μL of DMSO and carefully mixed and then determined at 540 nm using an enzyme-linked immunosorbent assay (ELISA) multiwell spectrophotometer.

5.2.3.2 Ishikawa Cell and Rat Assay for Detecting Antiestrogens

The cells are grown in 96-well plates in estrogen-free medium (phenol red free, with charcoal-stripped calf serum) and contain test compounds and antiestrogens at concentrations that are varied over several log orders. For the antiestrogen assay, to the cells, a range of concentrations of samples are added concurrently with 1-nM antiestrogens. After grown for 3 days, to determine AP activity, the cells are frozen, defrosted, and incubated with p-nitrophenylphosphate at room temperature, and the hydrolysis product p-nitrophenol is measured kinetically at 405 nm [50].

The specificity of the antiestrogenic activity is determined by using ERα and ERβ in ER element (ERE)-transfected human choriocarcinoma JAR cells, which are transfected with plasmids containing a consensus ERE fused to a firefly

luciferase reporter gene and separately with the expression vectors for either human ERα or human ERβ. JAR cells are routinely cultured in RPMI 1640 supplemented with 10% fetal bovine serum, 0.5% non-essential amino acids, and 1% PEST (100-U penicillin/mL and 100-μg streptomycin/mL). After seeded in six-well plates for 24h, cells are transfected using the Mirus Trans IT reagent in a serum- and antibiotic-free mixture of phenol-red free OptiMEM with 0.1–0.4-μg pC × N2 human ERα or pC × N2 h-ERβ, and a 0.75-μg 3 × ERE-TATA-Luc reporter constructed by introducing an HpaI/BglII fragment containing 3 × ERE-TATA into SmaI/BglII of the pGL3-Luc basic vector [51–53]. Medium is replaced with a phenol red-free RPMI containing 10% dextran-coated charcoal-treated calf serum and 0.5% non-essential amino acids. Twenty-four hours later, antiestrogens are added. Cells are incubated at 37°C in 5% CO_2 for 12h, harvested in 10-mM Tris-HCl/10-mM EDTA/150-mM NaCl, and centrifuged at 4000g for 4min. The supernatant is removed, the cell pellets are lysed in Lysis Buffer 2, and luciferase activity is measured.

After the AP assay and washing three times with PBS, the Ishikawa cells are lysed using 1% Nonidet P-40 and 0.1% sodium dodecyl sulfate in the presence of protease inhibitors. Before the antibody incubation, proteins (25μg/well) separated by SDS–PAGE on ice using 10% polyacrylamide gel are transferred to nitrocellulose membranes stained with Ponceau Red to ensure proper transfer. After blocking the membranes with 5% powdered milk in water, immunoblotting is performed. The blots are incubated with the ERα monoclonal antibody clone 6F11 overnight at 4°C. Using peroxidase-labeled horse antimouse secondary antibody and Chemiluminescence Reagent Plus, ERα is detected by Western blotting. Using a digital imaging analysis system, the intensity of the signal is analyzed. To normalize the amount of protein loaded in the gels, β-actin is used as an internal control.

The uterotrophic assay is performed with stimulation in immature rats [54]. Female SD rats (22 days old) are injected s.c. daily for 3 days with antiestrogens, control animals receive the vehicle (0.1-mL sesame oil), then animals are killed, and uteri are removed, dissected, blotted, and weighed. To determine whether antiestrogens have tissue-selective effects in cholesterol, uteri, and bone, ovariectomized female SD rats (250g) are injected with antiestrogens s.c. for 35 days, and then killed by exsanguination under ether anesthesia. The total cholesterol concentration of the serum is determined by a commercial chromogenic assay. The uteri are dissected, weighed, fixed in formalin, and imbedded in paraffin to prepare for 5-μm sections. Using the Openlab image analysis system, endometrial luminal epithelium and glandular cell height are measured. The tibia free of extraneous tissue are histomorphometrically analyzed. The bones fixed in 70% ethanol are dehydrated in graded ethanol and cleared in toluene. Then the specimens are infiltrated with increasing concentrations of methymethacrylate (MMA) and embedded in MMA [55]. After polymerization, MMA blocks are cut to size, sanded, and polished to the appropriate level to prepare 4–5-μm sections. The sections are mounted on gelatin-coated slides, stained with toluidine blue, and measured [56].

5.2.3.3 RT–PCR and Swine Assay for Detecting Anti-HEV Antibody

To choose seronegative pigs for inoculation, 75 SPF pigs (2 weeks old) are tested by ELISA for swine Hepatitis E virus (HEV) IgG antibodies. Before inoculation,

the pigs are allowed to acclimate to the research facilities for 1 week. Tissues (liver, heart, pancreas, or skeletal muscle) and feces of HEV-infected SPF pigs are collected at 3–7, 14–20, and 27–55 days postinoculation (DPI) and are pooled and stored at −70°C for inoculation [57]. Each inoculum is prepared as a tissue homogenate or fecal suspension (10%, w/v) in PBS and tested by a semiquantitative RT–PCR for swine HEV RNA. The positive control inoculum is a standard infectious pool of swine feces with a $10^{4.5}$ 50% pig infectious doses (PID_{50}) of swine HEV/mL.

Total RNA is extracted from 100 µL of each sample by TriZol reagent and tested by a nested PCR with primers located in the putative capsid gene (ORF2) [58, 59]. In the first round PCR, the fragment of 404 base pairs (bps) with the forward primer F1 (5′-AGCTCCTGTACCTGATGTTGACTC-3′) and the reverse primer R1 (5′-CTACAGAGCGCCAGCCTTGATTGC-3′) is formed. In the second round PCR, the fragment of 266 bps with the forward primer F2 (5′-GCTCACGTCATCT GTCGCTGCTGG-3′) and the reverse primer R2 (5′-GGGCTGAAC-CAAAA TCCTGACATC-3′) is formed. With R1 reverse primer and SuperScript II reverse transcriptase (GIBCO/BRL), total RNA is reverse transcribed at 42°C for 1 h and the resulting cDNA is amplified by PCR with ampliTaq Gold DNA polymerase. The PCR reaction is carried out for 39 cycles of denaturation at 94°C for 1 min, annealing at 52°C for 1 min, extension at 72°C for 1.5 min, and incubation at 72°C for 7 min. Overall, 10 µL of each round of PCR are mixed as the template. By gel electrophoresis, the amplified PCR products are examined. The virus titer of inocula is calculated and expressed as a genome equivalent (GE)/mL. After 7 to 21 days, serum samples of inoculated pigs are collected and tested by RT–PCR for swine HEV RNA.

Anti-HEV IgG antibodies in swine sera are detected using a standardized ELISA. A purified 55-kDa truncated recombinant putative capsid protein of human HEV strain Sar-55 is used as the antigen that cross-reacts well with the swine HEV. Peroxidase-labeled goat antiswine IgG is used as the secondary antibody. Duplicates per serum sample are used.

5.2.3.4 Antitubercular and Cytotoxic Assay

Using the microtiter plate alamarblue technique, the antitubercular activity is assessed against a nonvirulent strain of *Mycobacterium tuberculosis* ($H_{37}Ra$). As positive controls, isoniazid and kanamycin sulfate exhibit MICs in the ranges of 0.29–0.66 and 3.5–8.5 µM, respectively. According to the sulforhodamine B procedure, cytotoxicity is determined. MCF-7 (human breast adenocarcinoma), HeLa (human cervical carcinoma), KB (human oral epidermoid carcinoma), and HT-29 (colorectal carcinoma) are used as the target cell lines. After exposure to test samples, cell viability is determined colorimetrically at 515 nm. Dose-response evaluations yield a concentration mediating a 50% cytotoxic response (IC_{50}).

5.2.3.5 DNA Polymerase β Lyase Assay

Using terminal deoxynucleotidyltransferase + [α-^{32}P]ddATP, a 36-nucleotide oligodeoxyribonucleotide containing uridine at position 21 is labeled at its 3′-end and the product is subjected to 20% denaturing polyacrylamide gel electrophoresis for

purification. Using autoradiography, the interesting band is visualized and excised. By heating to 70°C for 3 min and then slow cooling to 25°C, the DNA substrate is annealed to its complementary strand. To 200 µL of 354-nM [α-^{32}P]-labeled double-stranded oligodeoxynucleotide with uridine at position 21, 10-mM Hepes-KOH (pH 7.4), 5-mM $MgCl_2$, 50-mM KCl, 10-mg/mL bovine serum albumin, 2.4 U of uracil-DNA glycosylase, and 3 U of AP endonuclease are added, incubated at 37°C for 20 min, and an apurinic (AP) site is created in the [α-^{32}P]-labeled double-stranded oligodeoxynucleotide. To 5 µL of the above reaction mixture, the test samples and 0.172 U of rat DNA polymerase β are added. After incubation at room temperature for 30 min, the reaction is terminated by adding 0.5-M $NaBH_4$ (50-mM final concentration) and incubated at room temperature for 10 min. The reaction products are incubated at 70–80°C for another 20 min, separated on a 20% denaturing polyacrylamide gel, and visualized by autoradiography.

A total of 200 µL of culture samples containing approximately 1.0×10^4 A549 cells (maintained in Kaighn's modification of Ham's F12 medium (F12K) with 2-mM L-glutamine supplemented with 1.5-g/L sodium bicarbonate and 10% fetal bovine serum at 37 °C in air containing 5% CO_2) are placed in each well of 96-well culture plates, treated with test samples, and incubated at 37°C for 48 h in air containing 5% CO_2. In the determination of cytotoxicity, the culture medium is replaced with 15 µL of 5-mg/mL MTT per well, the samples are incubated at 37°C for 4 h in air containing 5% CO_2, 200 µL of DMSO is added, and the OD_{570} value is obtained using a microplate reader.

5.2.3.6 HIV-1 Protease and Reverse Transcriptase Kinetic Assay

To the wells of a streptavidinecoated microtiter plate containing 20 µL of test sample solution and 4 ng of the HIV-1 RT in 20 µL of lysis buffer, 20 µL of the reaction mixture containing a homogenous template/primer hybrid ($(rA)_n(dT)_{15}$, 750-mA_{260nm}/mL final concentration) and a triphosphate substrate (dUTP/dTTP, 10-µM final concentration) are added. After the reaction is carried out at 37°C for 1 h, 200 µL of anti-digoxigenin-peroxide solution and ABTS [2,2–azino-bis-(3-ethyl benzothiazoline-6-sulfonic acid) diammonium salt] substrate are added for the coloring reaction. The absorbance of each well is measured at 405 nm with the reference wavelength at 490 nm and nevirapine as the reference compound. Using the same procedure mentioned above, except for the concentration of the enzyme solution (1 ng of the HIV-1 RT), the incubation time (30, 52, 80, 105, 130 min), and various concentrations of either the template/primer (1500, 750, 187.5 mA_{260nm}/mL) or the triphosphate substrate (20, 15, 10, 5, 2.5 mM) in the presence of the inhibitor, the enzyme kinetic assay is also performed. With a slight modified procedure to that mentioned above, the HIV-1 protease assay is performed. To the mixture of 1 µL of the solution of test compound in DMSO and 10.5 µL of the substr-ate solution (His-Lys-Ala-Arg-Val-Leu-(p-NO_2)-Phe-Glu-Ala-Nle-Ser-NH_2, 0.1 mg/mL in HIV-1 protease assay buffer), 0.5 µL of the recombinant protease solution (0.3 mg/mL) is added and incubated at 37°C for 15 min, the reaction is stopped by the addition of 1.2 µL of 10% trifluoroacetic acid, and the reaction mixture is diluted with 20 µL of water. The hydrolysate and the remaining substrate are quantitatively analyzed by HPLC [column, Inertsil ODS-3 (4.6 × 150 mm), a linear gradient of CH_3CN (15% to 40%) in 0.1% TFA, an injection volume of 20 µL, and a

flow rate of 1.0 mL/min, detection at 280 nm]. The hydrolysate and substrate are eluted at 8.61 and 10.84 min, respectively.

5.2.3.7 P-Glycoprotein Pump Assay

MCF-7R cells (human breast adenocarcinoma cell line, resistant to adriamycin) maintained at 37°C in humidified atmospheric air containing 5% CO_2 in nutrient mixture (F10/HAM, contains L-glutamine, with 10% fetal calf serum, 1% non-essential amino acids, 60-µg/mL tylosin, and 1% antibiotic/antimycotic solution) are seeded in the wells of 96-well tissue microtiter culture plates at 3×10^4 cells in 200 µL of medium per well, incubated at 37°C for 24 h in a humidified atmospheric air containing 5% CO_2, and the medium is replaced with fresh medium containing 0.3-µM rhodamine 6 G together with samples. To thorough mixing of 50 µL of each of these prepared mixtures, 450 µL of fresh medium containing 0.3-µM rhodamine 6 G is added. After incubation of the test compound, reserpine (positive control) or rhodamine alone (negative control) is added and the plates are incubated at 37°C for another 3 h. Then the cells are washed twice with 200 µL of ice-cold PBS and trypsinized with 100 µL of phenol-red free trypsin solution for 15 min, which is then transferred onto empty wells. Overall, 100 µL of 4% SDS in PBS is added and the plates are shaken for 2 h to solubilize the cells and release rhodamine 6 G, which is determined by measuring the fluorescence of the dye at excitation and emission wavelengths of 530/25 and 590/35 nm, respectively.

On Lab-Tek chamber slides, MCF-7R cells are seeded at 5×10^4 cells per chamber and incubated at 37°C for 24 h in a humidified atmospheric air containing 5% CO_2, and the medium is replaced with fresh medium containing 0.3-µM rhodamine 6 G with or without 50-µM reserpine, with 100-µg/mL samples in separate chambers of the slide. The cells are incubated at 37°C for another 3 h and imaged using fluorescence microscopy with a 510–560-nm band-pass excitation filter and a 590-nm long-pass emission filter set.

5.2.3.8 KIRA Assay

There are two different approaches using the KIRA format. The first approach, IGF-I KIRA, uses adherent MCF-7 cells derived from a human breast adenocarcinoma expressing an endogenous IGF-I receptor to measure the bioactivity of IGF-I [60]. MCF-7 cells are seeded in each well of a flat-bottomed 96-well culture plate and incubated overnight, the supernatants are decanted, and the plates are lightly blotted on paper towels. To each well, the medium containing either experimental samples or the recombinant IGF-I standards are added. The cells are exposed to ligand for 15 min, the supernatants are decanted, and the plates are blotted. After addition of lysis buffer containing Triton X-100, sodium orthovanadate, and a cocktail of protease inhibitors, the crude lysates are generated and then transferred to an ELISA plate coated overnight with a 3B7 antibody (5.0 mg/mL) and blocked with 0.5% BSA. After removal of unbound material, the degree of receptor tyrosine phosphorylation is quantified with biotinylated anti-phosphotyrosine monoclonal antibody followed by HRP-conjugated dextranstreptavidin, and visualized with the development of a tetramethyl benzidine (TMB) substrate. The absorbance is determined at 450 nm with a 650-nm reference wavelength.

The second approach, N-terminal polypeptide D (gD)·trkA KIRA using CHO cells stably transfected with a recombinant human trkA receptor with an gD flag, is developed to measure the bioactivity of NGF. A polypeptide flag is cloned onto the N-terminus or C-terminus of the full-length recombinant human receptor stably transfected into CHO cells. A 26-amino-acid polypeptide derived from HSV gD as a capture reagent in the ELISA phase of the KIRA and a mAb 3C8 antibody as the capture antibody are used.

5.2.4 HEPATOXICITY AND HEPATOPROTECTIVE ASSAY

Mitochondrial proliferation of the chemicals related to hepatocellular carcinomas and their hepatocarcinogenecity are important factors for health. The renal adenocarcinomagenecity, hepatic adenoma, and carcinomagenecity induced by chemicals can promote the formation of preneoplastic foci in rats or mice. The clonal growth of glutathione-S-transferase (GST-P) enzyme-altered foci and the histopathological change in the liver of rats or mice may relate to liver carcinogenesis of chemicals. In the liver injury induced by chemicals, such as CCl_4, Bacillus Calmette Guerin (BCG), and lipopolysaccharide (LPS), the activities of protein, glucose 6-phosphatase, amidopyrine *N*-demethylase, and aniline hydroxylase; the levels of hepatic triglycerides and lipid peroxidation; the concentrations of nitric oxide (NO), content of malondialdehyde (MDA), and superoxide dismutate (SOD); and the viability of thymocytes can be changed significantly. In the hepatocarcinogenesis induced by chemicals such as chloral hydrate, the body weight of B6C3F1 mice can be decreased significantly. Proliferation factor (PF) and hepatocyte growth factor (HGF) are involved in liver regeneration cascade and TGF-β-induced growth inhibition of CCL-64 cells; thus, PFs present in the partially hepatectomized rat serum can serve as an index of liver regeneration cascade and two cytokines (HGF and HGF) may result in an additive effect on proliferation. Based on these facts, the GST-P enzyme-altered foci assay [61], partial hepatectomy assay [62], hepatoprotective assay [63], immunological assay [64], body-weight-based liver tumor incidence assay [65], hepatocyte primary culture assay [66], and CCL-64 cell growth assay [67] are established.

5.2.4.1 GST-P Enzyme-Altered Foci Assay

According to the required levels (0%, 0.03%, 0.1%, and 0.3%), the test chemical is incorporated into an irradiated (6.0 kGy) powder diet MF. The stability of 0.1%, 0.03%, 0.5%, and 5.0% chemical in the prepared diets is previously confirmed for 6 weeks at room temperature. Male F344/DuCrj rats (5 week old) are given an approximately 1-week quarantine/acclimation period to monitor health conditions and body weights. The normal rats (6 week old) are randomly divided into 8 groups (18 rats each for groups 1–5, 9 rats each for groups 6–8). The rats of groups 1–5 receive an injection of the initiator N-nitrosodiethylamine (200-mg/kg body weight, i.p.) [68]. The rats of groups 6–8 receive an injection of the vehicle. Two weeks later, the rats receive an injection of the test chemical at the desirable dose for a suitable treating period. Three weeks after beginning the experiment, all rats are given two-thirds partial hepatectomy [69]. At week 8, all surviving rats are killed

under ether anesthesia and their organs in the thoracic and abdominal cavities are examined macroscopically. Their livers are immediately excised and weighed to calculate the liver-to-body-weight ratio. For the 4–5-mm thick sections, the cranial and caudal parts of the right lateral lobe and the caudal part of the caudate lobe of all surviving rats are fixed in 10% buffered formalin solution, embedded in paraffin wax, sectioned, and stained immunohistochemically for glutathione S-transferase analysis (GST-P, ABC method) [70]. All GST-P positive hepatocytic foci larger than 0.2 mm in diameter (the lowest limit for reliable evaluation) are measured using a color image processor, and the numbers and areas (foci/cm^2) of the liver section are calculated. By microscopic analysis, BrdU-positive labeling indices (LIs) are quantified by randomly counting the number of positive nuclei per 1000 hepatocytes or number per unit area (mm^2) in sections stained immunohistochemically for BrdU [71].

5.2.4.2 Partial Hepatectomy Assay

Male F344 rats (30 days old) acclimated for 4 weeks before the experiment are randomly divided into 3 groups. At week 0, the rats receive a single i.p. injection of the solution of N-nitrosodiethylamine (200 mg/kg) in 0.9% saline. Two weeks later, the rats receive daily gavage administration of corn oil or 0.1-mmol/kg test chemical in a corn oil vehicle through the remainder of the 8-week study. At week 3, all rats receive a partial hepatectomy. The rats are given food and water, and lighting is set on a 12-h light/dark cycle. On days 23, 26, 28, 47, and 56, at least five rats from each group are sacrificed by aortic exsanguination. Whole livers are removed, and the tissues are fixed in 10% neutral-buffered formalin, embedded in paraffin, serially sectioned at 5 µm, and mounted on microscope slides. Formalin-fixed sections are stained with hematoxylin and eosin to perform histopathological examination.

5.2.4.3 Hepatoprotective Assay

To induce liver injury, CF rats (150–200 g) and Swiss albino mice (20–30 g) of either sex are administered orally CCl_4 diluted with liquid paraffin. The animals of the vehicle control group are orally administered an equal volume of liquid paraffin. In hepatoprotective studies, four suitable doses of test compound and two standard doses of silymarin (25 and 50 mg/kg, p.o.) are fed to a respective group of rats 48 h, 24 h, and 2 h before and 6 h after CCl_4 (0.5 µL/kg, p.o.) intoxication. From the orbital sinus of all animals, blood is collected 18 h after CCl_4 intoxication for glutamic-pyruvic transaminase (GPT), glutamic oxaloacetic transaminase (GOT), and bilirubin analysis. In the posttreatment studies, the same doses of test compound and silymarin as mentioned for hepatoprotective studies are fed to rats 6 h, 24 h, and 48 h after CCl_4 (0.5 mL/kg, p.o.) intoxication. From all animals blood is collected 2 h after the last dose of test compound administration for GOT, GPT, and bilirubin analysis. The test compound and silymarin (50 mg/kg, p.o.) are fed to two different groups of rats at 48 h, 24 h, and 2 h before and 6 h after CCl_4 (100 µl/kg, p.o.) intoxication, with the remaining two groups served as CCl_4 and vehicle control. Eighteen hours after CCl_4 intoxication, all animals of the four groups are fasted overnight and killed by decapitation. Livers are immediately excised and divided into two

parts for preparing homogenate (10%, w/v), among which one part is homogenized in isotonic sucrose (0.25M) for determining protein and glucose 6-phosphatase activity, and for preparing microsomes by calcium precipitation to determine amidopyrine N-demethylase and aniline hydroxylase activities with spectrophotometric methods, in which NADPH is used instead of the NADPH generating system, and another part is homogenized in isotonic PBS (0.01M, pH 7.2, 0.15-M NaCl) for determining hepatic triglycerides and lipid peroxidation. The hepatoprotective activity is expressed as hepatoprotective percentage H and calculated by $H = [1 - (T - V)/(C - V)] \times 100$, wherein T is mean value of drug and CCl_4, C is mean value of CCl_4 alone, and V is the mean value of control-treated animals. In the determination of acute toxicity, different groups of mice (each ten) are fed with different doses of test compound, with one group with the same number of mice served as control. The animals are observed continuously for 1h and then hourly for 4h for any gross behavioral changes and further up to 72h for any mortality.

5.2.4.4 Immunological Assay

A suspension of 2.5mg of BCG (viable bacilli) in 0.2mL of saline is injected via the tail vein into each mouse, and 10 days later a solution of 7.5µg of LPS in 0.2mL of saline is injected. The mice are anesthetized with ether, sacrificed by cervical dislocation 16h after LPS injection, and trunk blood is collected into heparinized tubes (50U/mL) and centrifuged at 4°C and 1500rpm for 10min. Serum is aspirated and stored at −70°C until assayed as described below. The liver is also removed and stored at −70°C until required.

For the *in vivo* experiment, the mice are equally divided into 5 groups randomly, including normal, model control, and test compound groups (3 different doses). Mice in test compound groups receive suitable doses using an 18-gauge stainless steel animal feeding needle for 10 days before LPS injection. Mice in the normal and model control groups are fed the same volume of vehicle only. For the *in vitro* experiment, the Kupffer cells isolated from normal and BCG priming rats are divided into 7 groups randomly, including control cells, cells added with LPS (5µg/mL) alone, and cells added with LPS (5µg/mL) and the test compound.

The liver of normal rat is initially perfused through the portal vein with D-Hank's until blood free and finally by recirculation with Hank's containing 0.5-g/L collagenase IV until the vessels are digested (up to 20min). The liver is scraped using a cell scraper, filtered by a 100-µm filter, and stirred in Hank's containing 2.5-g/L pronase and 0.05-g/L DNase at 37°C for 20min. After three times of centrifugation and washing at 4°C and 300g for 10min in Gey's balanced salt solution (GBSS), the cells are centrifuged in an 180-g/L Nycodenz gradient at 2500g for 20min. Kupffer cells are carefully sucked by cusp-straws at the pearl layer inderphase. The purified Kupffer cell fractions are finally collected by centrifugal elutriation. The Kupffer cells are washed with Hanks' and resuspended in RPMI 1640 medium containing antibiotics (100-U/mL penicillin, 100-mg/mL streptomycin), 2-mM glutamine, and 10% fetal calf serum. Overall, 1-mL aliquots containing 1×10^6 cells are added to 24-well culture plates. The cells are incubated for 60min in a humidified atmosphere containing 5% CO_2 at 37°C. Nonadherent cells are removed, and adherent cells are washed twice with PBS. To observe the direct effect, the cells at a density of 1×10^6/mL are incubated with different concentrations of test compound. The cells

(1×10^6/well) are cultured for 48 h with 5-µg/mL LPS, the supernatants are collected, and the concentrations of TNF-α and NO are measured.

According to the *in vitro* liver injury model, BCG-induced Kupffer cells are isolated from the livers of the rats injected via the tail vein with 3 mg of BCG 10 days before, and hepatocytes are isolated from the normal rats. The hepatocytes (1×10^9/mL), different concentrations of test compound, and BCG-induced Kupffer cells (1×10^6/well) are cocultured for 48 h with 5-µg/mL LPS and the supernatants are collected. In a 96-well plate, 100 µL of cell culture supernatant and 100 µL of Griess reagent (10-g/L sulfanilamide and 1-g/L N-1-naphthylethylenediamine dihydrochloride in 2.5% phosphoric acid) are incubated at room temperature for 10 min. Absorbance at 540 nm is measured. The nitrite concentration is calculated by comparing samples with standard solutions of sodium nitrite produced in the culture medium.

Livers are thawed, weighed, homogenized with Tris-HCl (5 mM containing 2-mM EDTA, pH 7.4), and centrifuged (1000 g, 10 min, 4°C), and MDA and SOD in the supernatant are immediately analyzed. MDA in liver tissue is determined by the thiobarbituric acid method [72]. The assay for total SOD is based on its ability to inhibit the oxidation of oxyamine by the xanthine–xanthine oxidase system. The absorbance of the red nitrite produced by the oxidation of oxyamine is determined at 550 nm.

Thymocytes (2×10^6/well) from mice are cultured for 48 h in 96-well plates containing RPMI 1640 medium supplemented with 5-µg/mL concanavalin A and 0.1 mL of collected supernatant. Three hours before the termination of the culture, cells are pulsed with MTT stock (in sterile PBS, 5 mg/mL, stored in the dark at 4°C for up to 1 week, before use immediately filtered, 0.22 µm, to remove any formazan precipitate, 20 µL/well), returned to 37°C, and incubated for another 3 h. The plates are centrifuged at 1000 g for 10 min to form cell pellets and MTT formazan products. The supernatant is carefully aspirated without disturbing the pellets, and formazan is solubilized by adding isopropanol (100 µL of isopropanol : 200 µL of supernatant). Insoluble material is then removed by centrifugation at 1000 g for 10 min. The solubilized formazan in isopropanol is collected and distributed into 12-well flat-bottom ELASA plates at a final volume of 100 µL/well. Plates are read at 570 nm within 1 h of adding isopropanol.

5.2.4.5 Body Weight-Based Liver Tumor Incidence Assay

Addition to extra groups for high and low outliers, the B6C3F1 mice (at the 9-week age point) are assigned to 1 of 17 consecutive weight groups ranging from 20 to 57.5 g in 2.5-g intervals. Each weight group of mice developing a liver tumor is sorted for the calculation of the relative tumor risk. The mice with hepatocellular adenoma, carcinoma, or hepatoblastoma are designated as positive or otherwise designated as negative. The process is repeated for each age point to 68 weeks.

Approximately 4-, 5-, and 6-week-old male B6C3F1/Nctr BR mice are used at receipt, the initiation of controlled feeding, and on the first day of dosing, respectively. During the studies, the health of the mice is monitored. The dose for groups of 120 male mice receiving the solution of chloral hydrate in distilled water is 0, 25, 50, or 100 mg/kg (all at 5 mL/kg), 5 days per week for 104 to 105 weeks, each of which is divided into two dietary groups of 60 mice, and the vehicle controls

received distilled water only. The *ad libitum* fed mice are fed available *ad libitum*, and the dietary controlled mice are fed in measured daily amounts. All mice have water available *ad libitum*. At the 71-week age point, 12 mice of each diet/dose group are euthanized for pathological and biochemical evaluation. At the 110-week age point, the remaining 48 mice of each diet/dose group are fasted overnight before necropsy. Among them the mice with liver tumors refer to mice bearing single or multiple hepatocellular adenomas, hepatocellular carcinomas, and/or hepatoblastomas.

From week 21, the weight dataset of the first experimental group is imported with the preceding week's dataset as a reference. According to the predefined sort criteria (including whether the weight value for the previous week is outside either the 5% or the 12% confidence limits of the idealized weight curve or whether the mouse gains or loses weight in the preceding week), each mouse weight from the dataset is sorted into its appropriate weight group and assigned either the corresponding *ad libitum* or the weight-reduced tumor risk value from the tumor risk tables. The resulting tumor risk dataset in the appropriate week's column of a new table is stored and proceeded to the next week's dataset. According to all weekly datasets from 21 to 68 weeks, the mean tumor risk for each mouse in the dataset is calculated, the survival time for each mouse is imported, and the Poly-3 weighting time at risk factor (a_{ij}) for each mouse is calculated. The mean (cumulative) tumor risk dataset is sorted into 2% incremental percentage tumor risk groups, and the corresponding a_{ij} value for each mouse is assigned into the appropriate tumor risk group. This procedure can be adapted to sort individual data for each week rather than the means of all 48 weeks. The resulting tumor risk group table is used to calculate the mean tumor risk estimate and standard deviation of the experimental group to predict the survival-adjusted liver tumor rate, over all liver tumor rates and the number of animals bearing tumors.

5.2.4.6 Hepatocyte Primary Culture Assay

On anesthetic male SD rats (225–250 g) with sodium pentobarbital (65 mg/kg i.p), tracheotomy is performed. A catheter is flushed with heparin (200 U/mL) to prevent blood clotting of PE 240 polyethylene tubing that is inserted into the trachea to facilitate the respiration. By inserting PE 50 polyethylene tubing, the right femoral artery and vein of the rats are cannulated, and the rats are infused with 0.5-mL saline containing 1-mg/mL sodium pentobarbital/100-g body weight/h through the vein by a Syringe Infusion Pump to supplement fluid loss and maintain the anesthetic level. On the abdomen posteriorly from the xiphoid process of the sternum, a 3-cm median-line incision, which is sutured with two layers of the muscle and skin, is made. Using surgical silk (size 0), left lateral and median liver lobes are ligated and given the partial hepatectomy (2/3 PHX). At various time points after PHX, the diaphragm is cut, and within 2 min from the right ventricle of the heart, a blood sample (5–10 mL per rat) is drawn and centrifuged (2500 g, 20 min) for collecting plasma. In the preparation of serum, the blood is allowed to clot on ice for 10 min, then spun down, with the serum of non-PHX rats as 0 h control. For sham-operated rats, the liver is manipulated without PHX.

In the liver perfusion, the male SD rat (300 g) is anesthetized with sodium pentobarbital (65 mg/kg, i.p.). By surgical silk an 18 G, 1.25-in (32 mm) i.v. catheter is

used as the portal vein catheter tie to the vein. Through a catheter inserted into the inferior vena cava via the right atrium of the heart, the perfusion buffer is drained. The liver is perfused with 400 mL of nonrecycled oxygenated Ca^{2+}-Mg^{2+} free Dulbecco's PBS (DPBS, 2.68-mM KCl, 1.47-mM KH_2PO_4, 136.9-mM NaCl, 8.1-mM Na_2HPO_4, pH 7.4) containing 0.49-mM EDTA to reduce Ca^{2+} in the liver tissue, with 100 mL of DPBS without EDTA to wash out the EDTA in the system and with 100 mL of recycled oxygenated collagenase/Swim's 77 (0.25 mg/mL) with 5-mM Ca^{2+} for 10–15 min. Upon finishing perfusion, the liver is rinsed thoroughly with 10–20 mL of sterile DMEM. The liver is transferred into a sterile petri dish containing fresh medium. Using two forceps, the liver capsule membrane is slit, which is gently shaken and the cells are released into the medium. Two Spectra/Mesh N filters (70 μm, 40 μm, Spectrum) are used to filter the isolated liver cells to remove tissue chunks and cell debris. The cell suspension is filtered by low-speed differential centrifugation (300 g, 3 min, 4°C) for further purification. By aspiration the supernatant is discarded, the cell pellet is gently mixed with fresh medium, and the centrifugation procedure is repeated three times. Using the trypan blue exclusion method, viable cell concentration and percentage of nonhepatocytes is determined. In the purification of hepatocyte, 20 μL of trypan blue (0.4%) are added into 20 μL of cell suspension (dilution factor = 2), which is mixed and loaded onto the hemocytometer. All corner squares (64 squares/chamber) of the two chambers are counted (128 squares total; each square is 1 nL, 128 nL × 7.813 = 1 μL). Viable cells/μL = viable cells per 128 squares × 7.813 × 2. The final concentration is the average value of three separate countings. Viability (%) = viable cells/(viable + dead cells) × 100%. Nonhepatocyte (%) = nonhepatocyte/total cells × 100%.

Each well of six-well plates is coated with 20 μL of the solution of rat tail collagen (0.8-mg/mL double distilled H_2O with 0.1% acetic acid) and allowed to dry. To the well approximately 2 mL of DMEM/F-12 (supplemented with 25-mM sodium bicarbonate, 10-mM HEPES, 100-U/mL penicillin G, and 0.1-mg/mL streptomycin) is added. To each well the suspension of viable cells (final cell concentration, 100,000 cells/mL) are seeded and constantly mixed by agitation. The plates are incubated at 37°C overnight. When the attachment reaches the end, the medium is changed, mildly shaken, and aspirated. The wells are rinsed with 1 mL of medium and aspirated. From three randomly selected wells in the culture, the counts of the viable tarting-cell-number are calculated. Serum or plasma samples in 2 mL of fresh medium (10%) are added to wells, to which heparin (35-U/mL final) is added to prevent the medium from clotting during the culture. Cells grown in serum-free medium and in serum-free medium plus 100-ng/mL EGF and 20-mU/mL insulin are used as the negative and positive control, respectively. The medium is changed by aspiration at 24 h with no rinse. To each well, fresh medium with serum or plasma and other additives are added. At the end of 48 h, culture-attached hepatocytes are harvested and counted. The medium in each well is aspirated, serum or plasma-containing wells are rinsed once with saline and aspirated to wash off various plasma proteins. Overall, 400 μL of trypsin-EDTA is added to each well. The plate is covered and in the incubator for approximately 1 min and checked. The trypsin digestion is assessed. The plate is immediately placed on ice, and the serum of SD rats (40 μL, final concentration 10%) is added into each well to inhibit further trypsin digestion of the cells (440 μL total volume per well). On ice and using a pasteur pipet, the cells are gently blown from the bottom of the well. After

all cells are lifted, the cell suspension is transferred into a 1.5-mL Eppendorf tube and kept on ice for an immediate counting with no centrifugation or trypsin removal. In a plate (dilution factor = 1.25) 40 µL of cells and 10 µL of 0.4% trypan blue are mixed and loaded onto the hemocytometer.

5.2.4.7 CCL-64 Cell Growth Assay

Serial dilutions of test samples are prepared on 96-well flat-bottomed microplates with 100 µL of CM per well. Before the assay, to activate latent TGF-B, the samples are transiently acidified by first adding HCl to pH 2 and subsequently neutralizing with NaOH. CCL-644 cells (Mv-1-Lu) grown in RPMI 1640 supplemented with 10% FCS, 2-mM L-glutamine, and 40-µg/mL gentamicin (Complete medium, CM) are seeded at 1×10^4 cells/well and grown for 24 h in a total volume of 0.2-mL CM. After 20 h, the cells are pulsed for 4 h with 1 µCi/well of [methyl-^{3}H]thymidine and harvested with a Micromate 196 cell harvester. The concentration of TGF-β in the sample is determined by the growth inhibition caused by the sample, compared with a standard curve obtained by testing serial dilutions of porcine TGF-β. When the assay is used to measure HGF, the concentration is determined by this cytokine's ability to reverse the growth inhibitory effect of 350 pg/mL of TGF-β.

5.2.5 ANTI-INFLAMMATORY ASSAY

In the development of serious diseases, inflammatory is frequently involved. The development of inflammatory events may be induced by chemicals such as glucocorticoid; are regulated by endogenous factors such as tumor necrosis factor alpha (TNFα), enzymes and proteins such as copper and zinc-superoxide dismutase (SOD1), proinflammatory peptide substance P (SP), RGD peptides, interleukin-4 (IL-4), IL-10, interferon-γ (IFN-γ), cyclooxygenase-1 (COX-1), cyclooxygenase-2 (COX-2), 5-lipoxygenase (5-LOX), macrophage inflammatory protein (MIP)-1R, glucocorticoid regulated protein CD163, FK506 binding protein 51 (FKBP51), and monocyte chemoattractant protein-1 (MCP-1); implicated by cytokine such as interleukin-1 (IL-1); and mediated by adhesions such as fibrous adhesions and cell adhesions resulting from the receptor, such as $\alpha_{II}\beta_{III}$, human glucocorticoid receptor and chemokine receptors (CCR5), and banding. Based on these facts, the adhesion formation assay [73]; human peripheral blood mononuclear cell (PBMC) proliferation assay [74]; COX-1, COX-2, and 5-LOX assay [75]; CCR5 re-ceptor binding assay [76]; tissue binding affinity assay [77]; G93A-SOD1 transgenic mice assay [78]; mitogen-activated protein kinases (MAPK) p44 (ERK1) and p42 (ERK2) assay [79]; ELA4.NOB-1/cytotoxic T lymphocyte line (CTLL) cell assay [80]; and FKBP51 mRNA assay [81]; and Xylene-induced ear edema assay [82] are established.

5.2.5.1 Adhesion Formation Assay

For assessment of the neurokinin 1 receptor antagonist (NK-1RA) on peritoneal adhesion formation, a laparotomy is performed through a midline incision, and four ischemic buttons, spaced 1 cm apart, are created on both sides of the parietal

peritoneum by grasping 5 mm of peritoneum with a hemostat and ligating the base of the segment with a 4-0 silk suture. To assess the effects of NK-1RA on adhesion formation, peritoneal adhesions are induced in 42 male Wistar rats (200–250 g) that are randomized to experimental groups receiving the specific non-peptide NK-1RA, the test compound, or vehicle. In the initial study, the rats in the experimental group receive a 0.2-mL i.p. injection of 25-mg/kg NK-1RA twice a day for 2 days. At the time of surgery, 1 ml of a 0.75-mg/mL test compound is given as a peritoneal lavage, and the rats then received i.p. injection for 7 days. Control rats are similarly injected/lavaged with sterile vehicle. This experiment is repeated with 10-mg/kg NK-1RA per day. At day 7, all the rats are killed and the adhesions are quantified in a blinded fashion. Each rat receives a percent adhesion score based on the number of ischemic buttons with attached adhesions.

For assessment of NK-1RA on peritoneal tissue plasminogen activator (tPA) and PAI-1 expression and activity, the temporal expression pattern of tPA and PAI-l mRNA in peritoneal tissue collected from a 0.5-cm radius of the ischemic buttons are determined by RT–PCR analysis at days 0, 1, 3, and 7 after surgery. Based on the results, the effects of NK-1RA administration on tPA and PAI-1 mRNA and protein levels are determined at postoperative day 1 in pedtoneal tissue and fluid by RT–PCR ana1ysis and bioassay, respectively. The rats receive 5.0-mg/kg NK-1RA or vehicle per day. Control samples are collected from 6 nonoperated rats. All samples are immediately frozen in liquid nitrogen and stored at −80°C until used.

Total RNA is isolated from 50 mg of peritoneal tissue with the SV Total RNA Isolation System, and RT–PCR is conducted with the Gene-Amp RNA PCR System. To amplify tPA and PAI-1, the 28 cycles of 95°C, 60°C, and 72°C for 30 s each are used. In the amplification of tPA, the primer sets of 5′-TCTGACTTCGTCTGCCAGTG-3′ (sense) and 5′-GAG-GCCTTGGATGTGG TAAA-3′ (antisense) are used. In the amplification of PAI-1, the primer sets of 5′-ATCAACGACTGGGTGGAGAG-3′ (sense) and 5′-AGCCTGGTCATGTT GCTCTT-3′ (antisense) are used. Overall, 15 µL of PCR products are subjected to electrophoresis on 2% agarose gels containing 0.03-µg/mL ethidium bromide, and the quantitative level of the transcript is determined by scanned photographs of gels. Levels of mRNA expression are normalized to GAPDH, a constitutively expressed gene that does not vary among treatment groups.

Using the corresponding kits, the total levels of tPA and PAI-1 in peritoneal fluid samples are measured. From 12 vehicle-administered, 12 NK-1RA-administered (10.0 mg/kg per day), and 12 nonoperated control rats, peritoneal fluid is collected in 5-mM citrate and 0.1-M acetate for assessment of fibrinolytic activity caused by tPA activation of plasminogen. Overall, 1.0 µL of peritoneal fluid samples are run on 10% SDS polyaerylamide gels containing 0.1% gelatin and 0.002% plasminogen. After electrophoresis the gels are washed twice in 2%Triton X-100 and incubated overnight at 37°C in 0.1-M glycine (pH 8.3). The gels are stained with a 0.25% Coomassie blue solution, and PA activity is visualized as clear bands produced by plasmin lysis of gelatin. Determining the contribution of serine proteases, a 10-mM serine protease inhibitor, PMSF, is added to the developing buffer. In the identification of the zones of lysis corresponding to tPA activity, tPA and/or uPA are immunoprecipitated from peritonea1 fluid samples. To the mixture of 10 µL of peritoneal fluid and 10 µL of buffer containing 40-mM phosphate, 1-M

NaCl, 0.2% SDS, 2% Igepal CA-630, and 1% deoxycholate (pH 7.5), 1µg of tPA and/or uPA antibodies are added and incubated at 4°C overnight. To each sample, 10µL of a 50% UltraLink protein A/G slurry is added and incubated overnight at 4°C. Samples are centrifuged at 4°C and 16,000g for 1min, and the supematant (50%) is analyzed by zymography for comparison with human recombinant tPA and uPA standards.

5.2.5.2 PBMC Proliferation Assay

On removal of plasma the heparinized human peripheral blood from 60mL of healthy donors is centrifuged (4°C, 2000g, 10min), and the blood cells are diluted with PBS and centrifuged (1500g, 30min) [83]. After removal of red blood cells, the PBMC cell layers are collected, washed with cold distilled water and 10 × Hanks' buffer saline solution, and resuspended (2×10^6 cells/mL) in RPMI-1640 medium supplemented with 2% fetal calf serum, 100-U/mL penicillin, and 100-µg/mL streptomycin. In the determination of the lymphoproliferation, 100µL of the PBMC suspension is deposited into a 96-well flat-bottomed plate with or without 5-µg/mL phytohemagglutinin (PHA, with cyclosporin as a positive control) [84], into which solutions of various concentrations of test compounds are added, the plates are incubated at 37°C for 3 days in humidified atmospheric air containing 5% CO_2, tritiated thymidine is added, incubated for another 16h, and the cells are harvested on glass fiber filters using an automatic harvester and measured with a scintillation counting. In the determination of cell viability, approximately 2×10^5 T cells with or without PHA are cultured with 0.1% DMSO, solutions of various concentrations of test compounds are added, the plates are incubated for 3 days, the viable cell numbers are counted using a microscope with a hemocytometer following staining by trypan blue, and the percentage of viable cells is calculated. To analyze the cell cycle, 1mL of the PBMC suspension is added into a 6-well flat-bottomed plate with or without 5-µg/mL PHA [85], 25µg/mL of each test compound is added, the plates are incubated at 37°C for 3 days in humidified atmospheric air containing 5% CO_2, the medium is centrifuged, and the cells are harvested, washed with PBS, and fixed in 70% ethanol at −20°C for 30min. DNA is then stained with 4-µg/mL propidium iodide containing 100-µg/mL ribonuclease A. Flow cytometric analysis is conducted.

After incubation with PHA alone or in combination with solutions of varying concentrations of test compounds for 3 days, the medium is centrifuged, and PBMC (2×10^5 cells/well) supernatants are collected to quantify the concentrations of IL-2, IL-4, IL-10, and IFN-γ by means of enzyme immunoassays.

After stimulation with or without PHA and coculture with 25-µg/mL, each compound for 18h, the collected PBMC cells (5×10^6) are subjected to lysis with RNA-Beek and centrifuged, the supernatants are extracted with a phenol-chloroform mixture, and the extracted RNA is precipitated with isopropanol, pelleted by centrifugation, and redissolved in diethyl pyrocarbonate (DEPC)-treated H_2O. The concentration of the extracted RNA is measured using the optical density at 260nm.

In the synthesis of the first-strand cDNA, 1-µg aliquots of RNA are reverse-transcribed. The mixture of 1-µg RNA in 12.5µL of DEPC-treated H_2O and 20-µM oligodeoxythymidine (oligo dT) 18 is heated at 72°C for 2min, and

then quick-chilled on ice. To this mixture, 5.5 µL of concentrated synthesis buffer (50-mM Tris-HCl, pH 8.3, 75-mM KCl, 3-mM $MgCl_2$, 0.5-mM deoxynucleotides triphosphates (dNTPs), and 1 U ribonuclease inhibitor), and 10 U of moloney murine leukemia virus reverse transcriptase are added. The reaction mixture is incubated at 42°C for 1 h and then at 94°C for 5 min. To the reaction mixture, 80 µL of DEPC-treated H_2O is added and the mixture is stored at –20°C for use in the PCR. To 5 µL of the first-strand cDNA, 0.6-µM primers, 1.25-U Taq polymerase, 10-µL reaction buffer (2-mM Tri-HCl, pH 8.0, 0.01-mM EDTA, 0.1-mM dithiothreitol, 0.1% Triton X-100, 5% glycerol, and 1.5-mM $MgCl_2$) and 15.75 µL of water are added and the total volume is 25 µL. According to the air thermocycler, a denaturing temperature of 94°C for 45 s, annealing temperature of 58°C for 45 s, and elongation temperature of 72°C for 1 min for the first 25 cycles, and finally 72°C for 10 min, PCR is carried out and the amplified product is run on 1.8% agarose gels.

5.2.5.3 COX-1, COX-2, and 5-LOX Assay

For the COX-1 and COX-2 assay, the diluted solution of the test compound is incubated with COX-1 or COX-2 according to the standard method and then the enzyme reaction is initiated by the addition of [1-^{14}C]-arachidonic acid. From the incubation mediate, prostaglandin E_2 and prostaglandin D_2 (PED_2) are extracted to measure radioactivity. Indomethacin is used as a positive control. For the 5-LOX assay, the inhibitory activity of the test compound is evaluated. The test compound is incubated with 5-LOX (46 µg of protein) at 24°C for 10 min, and then the enzyme reaction is initiated by the addition of [1-^{14}C]-arachidonic acid (50 nCi). After 5 min, 4-M formic acid is added to terminate the enzyme reaction. Indomethacin is used as a positive control.

5.2.5.4 CCR5 Receptor Binding Assay

In the determination of chemokine receptor (CCR5) binding activity, a 96-well scintillation proximity assay (SPA) format and CHO cells overexpress-ing the human CCR5 receptor are used. From the CHO cells, MIP-1α and membranes are obtained, and after ^{125}I labeling, the former is converted into [^{125}I]-human MIP-1α. The solution of the test compound, 12.5% aqueous DMSO, 12 µg of membranes, 0.17-nM [^{125}I]-MIP-1α, 0.25 mg of Wheat Germ Agglutinin-SPA beads, and assay buffer (50-mM HEPES, 1-mM $CaCl_2$, 1-mM $MgCl_2$, 1% BSA, and a protease inhibitor cocktail), is incubated at room temperature for 5 h with shaking. The beads are settled for 2 h, and the total binding is measured via the radioactivity test. In the presence of 1-µM recombinant human MIP-1α, the nonspecific binding is defined. A IC_{50} of 2.7 nM of human MIP-1α is used as a reference.

5.2.5.5 Tissue Binding Affinity Assay

In hydrophobic teflon bags, the test compound and blood monocytes isolated from pooled buffycoats at a density of 2×10^8-cells/mL McCoy's medium supplemented with 20% fetal calf serum are cultured for 2 days. The monocytes are washed with

cold PBS (pH 7.4), incubated with BSA (1%) at 4°C for 30 min, washed with PBS, incubated with monoclonal antibody anti-CD163 (5–10 μg/mL) at 4°C for 45 min, washed with PBS, and incubated with FITC-labeled secondary antibody goat-antimouse IgG_1 in 1% BSA at 4°C for 30 min. At the last 3 min of the incubation, Propidium iodide is added to determine cell viability and to exclude dead cells using activated cell sorter (FACS) analysis (488 nm, 250 mW, logarithmic amplification).

Human lung cancer-free tissue from patients with bronchial carcinomas and receiving no glucocorticoids for the last 4 weeks before surgery is immediately washed with Krebs-Ringer-HEPES buffer (118-mM NaCl, 4.84-mM KCl, 1.2-mM KH_2PO_4, 2.43-mM $MgSO_4$, 2.44-mM $CaCl_2 \cdot 2H_2O$, and 10-mM HEPES, pH 7.4) and sliced into pieces of 1 mm^3 or deeply frozen immediately in liquid nitrogen and stored at −70°C.

The frozen human lung tissue is pulverized and homogenized in three aliquots buffer solution A (10-mM TRIS, 10-mM $NaMoO_4$, 30-mM NaCl, 10% glycerol, 4-mM DTT, 5-mM dichlorvos, and 1-mM Complete) with an Ultra Turrax mixer in an ice bath and then centrifuged at 4°C and 105,000 g for 1 h to prepare glucocorticoid receptors (30–60 fmol/mg cytosol [86]). The receptor binding experiments are performed according to the standard method [87]. The radiochemical purity of the labeled glucocorticoid is determined by HPLC, TLC, and scintillation counting.

5.2.5.6 G93A-SOD1 Transgenic Mice Assay

EOC-20 cells are grown in 75-cm^2 cell culture flasks with DMEM supplemented with 10% fetal calf serum and 20% L292 fibroblast-conditioned medium, transferred into 24-well cell culture plates, treated with the solution of test compound in DMSO or DMSO vehicle alone (1% final volume) for 30 min, and challenged with TNFα for 24 h. The culture medium is collected and assayed for determining the IC_{50} of the test compound that suppresses TNFα-induced NO_2^- by 50% via the determination of NO_2 [88]. The medium is removed, and DMEM lacking the phenol red indicator is added. To each well, MTS reagent [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethonyphenol)-2-(4-sulfophenyl)-2H-tetrazolium, inner salt] is added and incubated at 37°C for 30–45 min. The aliquots of media are collected and evaluated spectrophotometrically at 540 nm. The MTS solution prepared for the blank is incubated in the absence of cells. Viability is calculated as the ratio of OD_{540} in test compound-treated wells, relative to the same variable measured in wells treated with approximately 25-μM (typically 20 ng/mL) TNFα alone, after subtraction of the blank.

Transgenic mice expressing high copy numbers of human mutant G93A-SOD1 are maintained in the hemizygous state by mating G93A males with B6SJL-TGN females. The mice are fed *ad libitum* standard AIN93G diets or the same diets formulated with nordihydroguaiaretic acid at 2500 ppm; at 90 days of age, drug administration is started to demonstrate motor weakness and fine limb tremors [89]. At 90 days, 100 days of age, and subsequent 5-day intervals, mice are placed on a horizontal rod rotating at 1 rpm every 10 s until they fall from the rod; the mice that are no longer able to right themselves within 10 s of being placed on their sides are killed.

Using TRI reagent, total RNA is collected from the spinal cords of non-transgenic control and G93A+ transgenic mice. In the presence of avian myeloblastosis virus (AMV) RT using oligo(dT)$_{15}$ to prime the reaction, 5 µg of RNA samples are reverse transcribed. On completion, each reaction mixture is diluted with a TE buffer (10-mM Tris, 1-mM EDTA, pH 8.0) to a final volume of 50 µL. PCR amplification of a 309-bp 5LOX gene product is accomplished with Taq DNA polymerase, using the buffer and final concentrations of 1.5-mM $MgCl_2$, 0.2-mM dNTP, and 0.3-µM primer (5′-GGCACCGACGACTACATCTAC-3′, forward and 5′-CAATTTTG-CACGTCCATCCC-3′, reverse), of which the final volumes are 50 µL. A 353-bp PCR product of the β-actin primer (5′-CGGCCAGGTCATCACTATTG-3′, forward and ACT-CCTGCTTGCTGATCCAC-3′, reverse) is used as the normalization control. The optimal cycling conditions of PCR amplification of a 309-bp 5LOX gene product are at 94°C for 2 min, one cycle; at 94°C for 1 min, at 56°C for 1 min, and at 72°C for 1 min for 27 cycles; and at 72°C for 7 min, one cycle. The conditions for β-actin primers are the same as mentioned above, except that the annealing temperature is 54°C and performing 24 cycles. From each reaction, 25 µL of samples are collected, electrophoresed in 2% agarose/TBE [tris/borate/EDTA buffer (0.09-M Tris, 0.09-M borate, 0.002-M EDTA)] gels for 1.5 h, stained with ethidium bromide, and photographed with a NucleoVision imaging system. SL-29 fibroblast lysate is used as the positive control for 5LOX Western blots. On 4–20% gradient polyacrylamide gels, the electrophoresis is performed and the bands are visualized with chemiluminescence detection reagents. In the solution of 50-mM Tris-HCl (pH 6.8), 0.3-M NaCl, 1% β-mercaptoethanol, 1-mM phenylmethylsulfonyl fluoride, and 5-µM leupeptin, the spinal cord samples are homogenized and centrifuged (4°C, 30,000 g, 5 min). The supernanants are boiled for 10 min and centrifuged at 30,000 g and 4°C for 30 min, and the supernatants are dialyzed overnight against 50-mM Tris-HCl. From the heat-soluble fraction of total spinal cord lysate, microtubule-associated tau protein (C-tau) is cleaved and measured by sandwich ELISA, using affinity-purified monoclonal antibody 12B2 [90–92]. In immunohistochemical experiments, the terminally anesthetized mice are successively perfused transcardially with PBS (pH 7.4) and 4% paraformaldehyde in 0.1-M phosphate buffer. The spinal cord is collected, and the lumbar L5 region is processed for paraffin embedding. Serial cross sections of 5 µM thickness of the L5 spinal cord region are prepared for immunostain with antibodies to glial GFAP. In the absence of primary antibody, negative immunohistochemical controls are treated in the same way. GFAP-labeled sections are counterstained with hematoxylin.

5.2.5.7 MAPK p44 (ERK1) and p42 (ERK2) Assay

By RT–PCR from PMA-treated THP-1 cells, cDNA encoding CCR2B is isolated and subcloned into the expression vector pXMT3-neo [93], which contains an adenovirus late promoter and neo- and DHFR-selectable markers. After transfection with pXMT3-neo-CCR2B, selection with G418, amplification with methotrexate, and clone of CHO DUK-X cells, the resultant CHO-CCR2B cell line is cultured with modified MEMα (without ribonucleosides and deoxyribonucleosides) containing Glutamax-I, 100-U/mL penicillin, 100-µg/mL streptomycin, 10% (v/v) dialyzed FBS, and 80-nM methotrexate. Parental CHO cells are cultured with original MEMα containing 100-U/mL penicillin, 100-µg/mL streptomycin, and 10% (v/v)

FBS, split twice per week by incubation for 5 min with an enzyme-free cell dissociation buffer, and reseeded at a density of 1–2 × 10^4 cells/cm^2. Before an assay, the cells are seeded in methotrexate at 2 × 10^4 cells/well in flat-bottomed 96-well tissue culture plates, allowed to attach for 6 h, washed with 250-μL/well PBS, and incubated overnight in methotrexate containing endotoxin-free BSA (0.1%, w/v).

After preincubation of 60 μL of 20-nM MCP-1 with 60 μL of 0.4–1.8-μg/mL mAb at 37°C for 30 min, 50 μL of the MCP-1-mAb solution is added. The cells are preincubated at 37°C for 45 min with the solution of test compound in 50 μL of serum-free medium. After the addition of 50 μL of 20-nM MCP-1, the cells are incubated at 37°C for 5 min, the medium is replaced by 100-μL/well methanol equilibrated at −20°C, incubated at −20°C for another 20 min, and then washed three times with PBS containing Triton X-100 (0.1%, w/v). The cells are incubated with H_2O_2 (0.6%, v/v) in washing buffer for 20 min and washed as above, by which the activity of endogenous peroxidase is quenched. By adding a 250 μL/well assay buffer (washing buffer containing fraction V BSA, 5%, w/v) and incubating at room temperature for 1 h, the nonspecific binding sites are blocked. Then, the solution is replaced by a 100-μL/well monoclonal anti-phospho-ERK antibody (1 μg/mL in assay buffer). After incubating at 37°C for 1 h and washing three times with washing buffer, to the plate, a 100-μL/well goat-antimouse-IgG coupled with horseradish peroxidase (0.5 μg/mL in assay buffer) is added. After incubation at room temperature for 1 h and the plate is washed six times with washing buffer, 100 μL/well of tetramethylbenzidine is added. After color development for 10–30 min, the reaction is stopped by adding 50 μL of 2-M H_2SO_4 and the plates are read at 450 nm.

5.2.5.8 ELA4.NOB-1/CTLL Cell Assay

The ELA4.NOB-1 cells and CTLL cells maintained in RPMI 1640 containing 2-mM glutamine, 40-μg/mL gentamicin, and 100-U/mL penicillin, are transferred into a tissue culture medium (TCM) containing 5% heatinactivated fetal calf serum (FCS) and 10% FCS and recombinant human L-2 (100 U/mL), respectively. Cell lines are centrifuged (room temperature, 400 g, 1 min) and washed twice in fresh TCM supplemented with 10% FCS by resuspension and centrifugation. By enumeration using trypan blue (0.4%, w/v) in saline, ELA4.NOB-1 and CTLL cells are adjusted to 1 × 10^6 and 4 × 10^4 viable cells/mL, respectively. To 96-well round-bottom microtiter plates containing 100 μL of cytokine (control) or test compound, 50 μL aliquots of each cell suspension are placed. After incubation in air containing 5% CO_2 at 37°C for 24 h, the cells are treated with 50 μL of 2-μCi/mL tritiated thymidine, incubated for another 24 h, harvested onto printed filtermats that are dried at 30°C for 1 h and heat sealed into sample bags containing 4.5 mL of β-scintillant, and the radioactivity (cpm) is measured.

To each well containing 100-μL aliquots of the standard dilutions, 50 μL of ELA4.NOB-1 and 50 μL of CTLL cell suspensions are added. Using human recombinant IL-2 (0.025–1.6 U/mL) or test compound, the integrity of CTLL responses in the absence of ELA4.NOB-1 cells is measured. Human recombinant IL-1ra (0.1–100 ng/mL), ultrapure natural human TGF-β1 (0.01–10 ng/mL), and test compound are tested on ELA4.NOB-1 and CTLL cocultures in a similar way, generating standard dose response curves for these cytokines. In the tests of the effects of

IL-1ra and TGF-β1 on IL-1 induced activity in the coculture bioassay and on IL-2 induced CTLL proliferation, serial dilutions of IL-1β (0.78–50 pg/mL), IL-2 (0.025–1.6 U/mL), IL-1ra (1–100 ng/mL), TGF-β1 (0.01–10 ng/mL), and test compound in TCM supplemented with 10% FCS are used. Overall, 50-μL aliquots of each dilution of IL-1ra and IL-1β are dispensed and pipetted into 96-well microtiter plates, respectively, and 50 μL of the suspension of ELA4.NOB-1 and CTLL cells are aliquoted into each well, incubated, and treated with ^{3}H-thymidine as described above; similar assays are set up for IL-1ra and IL-2, for TGF-β1 and IL-1β, and for TGF-β1 and IL-2.

5.2.5.9 FKBP51 mRNA Assay

Within a 2-week period between 9 and 10 h by venapuncture, the blood of nine healthy controls without a history of GC medication (37 years old) and one GC hyposensitive patient harboring one nonfunctional GC receptor allele and resulting in a net functional GC receptor expression of approximately 50% is collected in sodium heparin tubes [94], and centrifuged, and the isolated PBMC are washed twice with RPMI 1640 and resuspended in assay medium consisting of RPMI 1640 supplemented with 4-mM L-glutamine, 100-U/mL penicillin, 100-μg/mL streptomycin, and 10% dextran-coated charcoal steroid-stripped fetal calf serum at 0.5×10^6 cells/mL. Overall, 1-mL aliquots of the PBMC suspension are added onto 24-well plates and incubated overnight at 37°C in humidified atmospheric air containing 5% CO_2. To the medium, dexamethasone (DXM) or the test compound is added and incubated for another 24 h to isolate RNA. For activation of PBMC, 0.1-mL aliquots of 0.5×10^5 cells are added onto a 96-well round-bottom plate and incubated with 1.5-μg/mL etanus toxoid for 9 h. Seventy two hours later, DXM is added. Then 96 h later, RNA is isolated. In a simultaneous control experiment, 78 h later, 1μCi 3H-thymidine is added, the cells are harvested, and incorporated radioactivity is determined.

For purification of PBMC subsets, cells are isolated, washed twice, resuspended in PBS at 1×10^7 cells/mL, incubated at room temperature for 30 min with phycoerythrin labeled primary antibodies (mouse-antihuman CD20, CD4, CD8, or CD14), and washed twice with PBS. The PBMC is resuspended in PBS at 1×10^8 cells/mL, incubated at 4°C for 30 min and labeled with goat-anti-mouse IgG, and washed and resuspended in 0.5 mL of PBS. The labeled and unlabeled PBMC are separated, resuspended in assay medium, divided into 0.1-mL aliquots onto a 96-well round-bottom plate, and incubated overnight. To the wells, DXM is added and incubated for another 24 h to isolate RNA.

For real-time PCR performed on the LightCycler, after the isolation by use of the TriPure reagent and reverse transcription by use of MMLV-RT RNase H Minus of RNA, the synthesized cDNA is diluted 20–40 times in ddH_2O [95]. To calculate the relative expression level of the genes of interest, the relative expression level of the housekeeping gene β_2-microglobulin (β_2m) in each sample is determined. Real-time PCR is performed in 10-μL medium containing 5.0 μL of diluted cDNA (0.5 pmol/μL each primer), 10% either DNA master SYBR-green I solution (for the FKBP51 and β_2m PCR) or DNA hotstart mixture (for the FKBP12, FKBP13, FKBP22, FKBP25, FKBP52, and Cyp40 PCR), and an optimal concentration of $MgCl_2$ (4-mM β_2m PCR, 3-mM FKBP51 PCR). The mixture is denatured at 95°C

for 30 s and 10 min for DNA Master I kit and Fast Start kit, respectively, and subjected to up to 40 amplification cycles: denaturing 15 s at 95°C, annealing 10 s at 56°C for β2m or at 67°C for FKBP51, and elongation 30 s at 72°C. A single measurement of fluorescence is taken after each elongation step at 82°C.

5.2.5.10 Xylene-Induced Ear Edema Assay

Male Kunming mice (about 25 g) are randomly divided into three groups of 12 mice, namely the test group, vehicle control group, and positive control group. The mice in the vehicle control group are administrated orally a suspension of Aspirin in CMC at a dosage of 20 mg/kg, and a concentration of 0.3 mg/mL, whereas the mice in the test group are administrated orally a suspension of test compound in CMC at a dosage of 20 mg/kg, 4.0 mg/kg, and 0.8 mg/kg, and a concentration of 2.0 mg/mL, 0.4 mg/mL, and 0.08 mg/mL. Thirty minutes later, 0.03 mL of xylene is applied to both the anterior and the posterior surfaces of the right ear. The left ear is considered a control. Two hours after xylene application, the mice are killed and both ears are removed. Using a cork borer with a diameter of 7 mm, several circular sections are taken and weighed. The increase in weight caused by the irritant is measured through subtracting the weight of the untreated left ear section from that of the treated right ear section.

5.2.6 THROMBUS-RELATED ASSAY

A series of events such as the platelet aggregation, fibrinogenesis, fibrin adhesion, fibrin aggregation, and vascular inner wall injury are implicated in the thrombosis. Thus the thrombosis, antithrombosis, and thrombolysis may relate to antiplatelet aggregation [96], chemical- and electrical-induced blood vessel injury [97, 98], thread-induced fibrin or platelet adhesion [99], euglobulin clot lysis time [100, 101], fibrinolytic area [102], and reduction of thrombus mass[103, 104].

5.2.6.1 Antiplatelet Aggregation Assay

Platelet-rich plasma is prepared by centrifugation of normal rabbit blood anticoagulation with sodium citrate at a final concentration of 3.8%. The platelet counts are adjusted to 2×10^5/μL by the addition of autologous plasma. Platelet aggregation tests are conducted in an aggregometer using the standard turbidimetric technique. The agonists used may be either the usual platelet-activating factor (PAF, final concentration 10^{-5}–10^{-7} M) and adenosine diphosphate (ADP, final concentration 10^{-5}–10^{-7} M) or thrombin and collagen. The effects of the tested compound on PAF or ADP-induced platelet aggregation are observed. The maximal rate of the platelet aggregation (Am%) is represented by the peak height of the aggregation curve.

5.2.6.2 Ferric Chloride-Induced Thrombosis Assay

After overnight fasting, male SD rats (320–380 g) are administered orally water (blank control), test compound (15, 30, 60 mg/kg), and aspirin (positive control, 30 mg/kg), and they are anesthetized with urethane (1.5 g/kg i.p.) at 90 min after

the oral administration. The experiments are carried out according to the modified method described by Kurz et al. [97]. The left common carotid artery is isolated carefully, and a plastic sheet is placed under the vessel to separate it from the surrounding tissue. The surface of carotid artery is covered with a 4×0.5-cm cotton sheet saturated with 300 μL of $FeCl_3$ solution (25%, w/v) for 15 min. Then, the injured carotid artery segment (0.6 cm) is cut off, from which the formed thrombus is taken out. After drying for 24 h at room temperature in a dehumidifier, the dried weight of the thrombus is measured.

5.2.6.3 Electrical Stimulation-Induced Arterial Thrombosis Assay

After overnight fasting, male SD rats (250–350 g) are anesthetized with urethane (1.5 g/kg, i.p.). The left carotid artery is isolated carefully. A plastic sheet is placed under the vessel to separate it from the surrounding tissue. Thrombus formation is induced with the modified Hladovec method [98]. The holder incorporates two electrodes, and the temperature sensor is fixed under the exposed carotid artery. Then, the rats are administered intravenously by NS (blank control), test compound (5, 10, 20 mg/kg), and aspirin (4 mg/kg), respectively. After 5 min, a current of 3 mA is delivered for 3 min. With thrombus formation, the temperature of carotid blood is abruptly decreased. The occlusion time (OT) is measured through the temperature sensor and timer on the electric thrombosis stimulator. The rate of thrombosis inhibition is calculated according to as follows: thrombosis inhibition (%) = $(A_1 - A)/A \times 100\%$, where A is the OT of the control group and A_1 is the OT of agent groups.

5.2.6.4 Thread-Induced Thrombosis Assay

Male SD rats (320–380 g) are treated with water (blank control), test compound (15, 30, 60, 120 mg/kg), and aspirin (positive control, 30 mg/kg, b.i.d. for 2.5 d i.g.) and anesthetized by intraperitoneal injection of urethane (1.5 g/kg) at 75 min after the last dose. The arteriovenous shunt operation is carried out as the method described by Umetsu and Sanai [99]. The left jugular vein and the right carotid artery are annulated with a 4-cm-long polyethylene tube (o.d. 1 mm) with heparin (50 U/kg) injection intravenously for anticoagulation. These catheters are connected to the ends of a 15-cm-long polyethylene tube (o.d. 2 mm) containing a 5-cm-long suture silk thread (no. 4) measured wet weight. At 120 min after the last treatment, the blood flowing through the shunt is confirmed for 15 min. The silk thread with thrombus is gently removed and measured immediately for the wet gross weight. The thrombus wet weight is determined by subtracting the premeasured silk wet weight from the gross weight. The rate of thrombosis inhibition is calculated as follows: thrombosis inhibition (%) = $(A - A_1)/A \times 100\%$, where A is the thrombus wet weight of the control (water) and A_1 is the weight after treatment with the agents.

5.2.6.5 Euglobulin Clot Lysis Time (ECLT) Assay

The rabbit euglobulin clots are prepared according to a published method [100, 101]. Plasma diluted at 1:20 in distilled water is precipitated at pH 5.7 with acetic

acid (0.25%). After 30 min at 4°C, the suspension is centrifuged at 2000 g for 15 min and the precipitate is resuspended to the initial plasma volume with 50-mM sodium barbiturate buffer (pH 7.8, containing 1.66-mM $CaCl_2$, 0.68-mM $MgCl_2$, and 93.96-mM NaCl). To the rabbit euglobulin clots, NS (blank control), UK (positive control), or test compound is added and the ECLT or time to clot lysis is determined in a 96-well microtiter plate.

5.2.6.6 Fibrinolytic Area Assay

The fibrinogen–agarose mixture is prepared and coagulated with thrombin in plastic dishes according to a published procedure [102]. The fibrinogen–agarose mixture is prepared by mixing equal volumes of 0.3% of rabbit fibrinogen and 0.95% of agarose solutions, both dissolved in 50-mM sodium barbiturate buffer (pH 7.8). The fibrinogen–agarose mixture is coagulated with 100 mL of thrombin (100 U/mL) in plastic dishes (90 mm diameter × 1 mm depth). After 30 min at 4°C, an adequate number of wells, 5 mm in diameter, are perforated. To determine fibrinolytic activity, 30 μL of NS (blank control), UK (positive control), or test compound is added to the corresponding well. The plate is incubated, and areas of lysis are quantified by lysis area.

5.2.6.7 Thrombolytic Assay

Male Wistar rats (200–300 g) are anesthetized with pentobarbital sodium (80.0 mg/kg, i.p.). The right carotid artery and left jugular vein of the animals are separated. To the glass tube containing 1.0 mL of blood obtained from the right carotid artery of the rat, a stainless steel filament helix (15 circles; 15 mm × 1.0 mm) is added immediately. Fifteen minutes later, the helix with thrombus is carefully taken out and weighed. It is then put into a polyethylene tube that is filled with heparin sodium (50-U/mL NS), and one end is inserted into the left jugular vein [103, 104]. Heparin sodium is injected via the other end of the polyethylene tube as the anti-coagulant, after which the test compound is injected. The blood is circulated through the polyethylene tube for 90 min, after which the helix is taken out and weighed. The reduction of thrombus mass is recorded.

5.2.7 IMMUNOMODULATING ASSAY

Immunomodulation not only relates to a series of physiologic and pathologic phenomena, but also it can be estimated by related reaction cells, such as mast cells, DCs and NK cells, and level of cell factors such as interleukin, interferon, tumor necrosis factor, and transforming growth factor. Based on those facts, the rat mast cell and rabbit aortic assay [105], dendritic cell assay [106], lymphoid organ assay [107], IFN-γ assay [108], anti-rHuEPO NAb assay [109], and chemotaxic assay [110] are established.

5.2.7.1 Rat Mast Cell and Rabbit Aortic Assay

The ice-cold PBS (10 mL, 137-mM NaCl, 2.68-mM KCl, 0.91-mM $CaCl_2$, 8.1-mM Na_2PO_4, 1.47-mM KH_2PO_4, 0.91-mM $MgCl_2$, 5.6-mM glucose, and 20.0-mM

HEPES) is injected (i.p.) into male Wistar rats (200–250 g). Approximately 90–120 s later, PBS is collected and peritoneal is subsequently washed by 5 mL and 10 mL of PBS. The washing PBS are also collected and combined with first PBS, followed by centrifugation (200 g, 5 min, 4°C). After washing twice with PBS, the pellet is resuspended into 10 mL of PBS. From the rat, peritoneal lavage mast cells are isolated.

Preincubation of 1.8 mL of mast cell suspensions are carried out at 37°C for 10 min, and 0.1 mL of test compound is added to stimulate the mast cells, which are cooled in ice to terminate histamine release. After centrifugation (100 g, 10 min, 4°C), to the supernatant and the pellet, an equal volume of 0.8-M $HClO_4$ and twice volume of 0.4-M $HClO_4$ are added, respectively. A mixture of 125 µL of 5-M NaOH, 0.4 g of NaCl, and 2.5 mL of n-butanol is added to 1-mL solution of test compound, the mixture is centrifuged (200 g, 1 min, room temperature) and separated. The upper organic phase is mixed with 2 mL of 0.1-M NaOH saturated with NaCl and centrifuged (200 g, 1 min, room temperature), and the procedure is repeated, of which the upper organic phase is mixed with 2 mL of 0.1-M HCl and 7.6 mL of n-heptane. The lower aqueous phase (1 mL) is mixed with 0.1 mL of 10-M NaOH. By incubation with 0.1 mL of o-phthalaldehyde (10-mg/mL methanol) at room temperature for 4 min to perform the histamine-o-phthalaldehyde conjugation, and by addition of 0.6 mL of 3-M HCl to terminate the conjugation. The fluorescence of histamine-o-phthalaldehyde conjugate is assessed at 450 nm with emission excitated at 360 nm.

The thoracic aorta of male Japanese White rabbits (3–3.5 kg) is cut into helical strips (approximately 4 mm wide and 20 mm long), and the endothelium is removed by gently rubbing the endothelial surface with cotton pellets. In 1 mL of organ bath containing the modified Krebs–Ringer–bicarbonate solution (120-mM NaCl, 4.8-mM KCl, 1.2-mM $CaCl_2$, 1.3-mM $MgSO_4$, 25.2-mM $NaHCO_3$, 1.2-mM KH_2PO_4, 5.8-mM glucose), the strips are mounted and suspended. With a force-displacement transducer connected to a polygraph muscle, the tensions of the strips are recorded isometrically. A passive tension of 1 g is initially applied and the strips are equilibrated for 60 min, after which, 60-mM NaCl in the modified Krebs–Ringer–bicarbonate solution is replaced by equimolar KCl for precontraction of the strips. Reaching a steady level of the response, the experiment is started. Contractile response to histamine is normalized with that of high K^+.

5.2.7.2 Dendritic Cell (DC) Assay

Before being used either for DC culture or for preparing T cells, human peripheral blood mononuclear cells (PBMCs) isolated from freshly leukapheresed blood are centrifuged and cryopreserved in 90% autologous serum and 10% DMSO. By negative depletion and using anti-HLA-DR monoclonal antibody-conjugated paramagnetic beads from allogeneic PBMCs, enriched T cells are prepared. The cells possessing potential costimulatory function are removed from the PBMCs, as suspension each batch of which is tested for the presence of any remaining B cells, monocytes, and 80–90% T cells. Using cell-specific paramagnetic bead preparations and by biomagnetic separation of the stimulators, B cells and T cells are purified and the purity of each cell type is greater than 90%, as determined by flow cytometry.

The cryopreserved PBMCs are thawed in warm AIM-V medium, washed with PBS, and resuspended in Opti-MEM medium supplemented with 1% heat-inactivated autologous plasma to prepare (5–10) $\times$ 10^6 cells/mL suspension. The suspension of 1×10^9 cells is transferred into T-75 culture flasks and cultured for 1 h, the nonadherent cells are resuspended, aspirated out, and stringently washed with cold PBS to remove loosely adherent cells. To each flask, 1.5 $\times$ 10^9 Opti-MEM medium containing 5% heat-inactivated autologous plasma, 500-U/mL rhGM-CSF, and 500-U/mL rhIL-4 are added and the adherent cells are incubated for 6 days. These DCs are then treated either with BCG alone or BCG plus IFN-γ for 24 h.

In the COSTIM bioassay, allogeneic T cells are thawed in warm AIM-V culture media, and washed with and resuspended in PBS at 1×10^5 DCs or 1×10^6 T cells/mL. To each triplicate well of a U-bottom 96-well plate, 100 µL of 1×10^4 DCs and 100 µL of 1×10^5 allogeneic T cells are successively added, and with or without 0.005-µg/mL anti-CD3 monoclonal antibody, which is incubated at 37°C for 44 h in humidified atmospheric air containing 5% CO_2. A total of 0.5 µCi Tritiated (^{3}H)-thymidine in 50 µL of AIM-V is added to each well, cultured for the last 18 h, the cells are harvested, and the incorporated radioactivity is quantified. Before 1 h of adding T cells and anti-CD3, the sterile, azide-free, and low-endotoxin IgG1 monoclonal antibodies specific for CD54, CD80, CD86, and an isotype control (BD Pharmingen) are added to the DCs at 1 µg/well to observe the costimulatory molecule block. In the mixed lymphocyte reaction (MLR), the cryopreserved DCs (stimulators) and T cells (responders) are thawed in warm AIM-V media, washed with PBS, and resuspended in PBS at 1×10^5 DCs or 1×10^6 T cells/mL. To each well of a U-bottom 96-well plate, 100 µL of 1×10^4 DCs and 100 µL of 1×10^5 allogeneic T cells are successively added and incubated at 37°C for 6 days in humidified atmospheric air containing 5% CO_2. A total of 0.5 µCi Tritiated (^{3}H)-thymidine in 50 µL of AIM-V is added to each well, cultured for the last 18 h, the cells are harvested, and the incorporated radioactivity is quantified.

5.2.7.3 Lymphoid Organ Assay

After a 4-week acclimation period, male Wistar rats (4 weeks old, 225–250 g, housed in polypropylene cages in a environment-controlled room maintained at 22°C, 55% relative humidity, and a 12:12 h light/dark cycle) are allocated to six groups (n = 15–20 rats each). The untreated group is used as control (maintained on basal diet and sacrificed at weeks 4 and 30). During weeks 1 and 2, the DMBDD, DMBDD/PB, and DMBDD/2-AAF groups are sequentially treated with initiators DEN (N-nitrosodiethylamine, 100 mg/kg, i.p.), MNU (N-methyl-N-nitrosourea, 20 mg/kg, i.p., four times, two doses per week), and BBN (0.05% in drinking water during 2 weeks); during weeks 3 and 4, DHPN and DMH groups are sequentially treated with DHPN (0.1% in drinking water during 2 weeks) and DMH (1,2-dimethylhydrazine, 40 mg/kg, s.c., four times, two doses per week). At the end of the week 4, some animals of the DMBDD group are killed and the remainder is maintained on a basal diet until week 30. After the initiation, the DMBDD/PB and DMBDD/2-AAF groups are supplied with phenobarbital (PB, 0.05%) and 2-acetylaminofluorene (2-AAF, 0.01%) in the diet for 25 weeks, respectively. From the sixth week until week 30, two noninitiated groups receive PB or 2-AAF in the diet. At the week 4 or 30, all animals are killed under pentobarbital (45 mg/kg)

anesthesia. The liver, kidneys, spleen, thymus, mesenteric lymph nodes, and bone marrow removed from all animals are fixed in buffered formalin for 48h for tissue processing and histological analysis. Only at week 30 are the lung, small and large intestine, and Zymbal's gland examined. After removal of the liver, the kidneys, spleen, and thymus are weighed immediately. The spleen is cut in two halves for evaluation of cytokines and histological analysis, respectively. All removed organs are embedded in paraffin and stained with hematoxylin and eosin for histological analysis [111]. The suspensions of spleen cells dispersed in a Petri dish containing RPMI-1640 culture medium are centrifuged; resuspended in RPMI-1640 culture medium supplemented with 20-mg/mL gentamycin, 2-mM glutamine, and 10% inactivated fetal calf serum; and washed twice by centrifugation at 1500g for 10min. To aliquots of 2×10^6 cells/mL (500µL/well) in 24-well flat-bottom microtiter plates, RPMI-1640 (500µL/well) or Concanavalin A (CON A-2.5µAg/mL, 500µL/well) or Staphylococcus aureus Cowan's strain 1 (SAC-1:5000, 500µL/well) is added and the plates are incubated at 37°C for 72h in humidified atmospheric air containing 5% CO_2. After incubation, the collected supernatants are stocked at −70°C for quantification of cytokines. CONA *in vitro* stimulated samples are used to quantify IL-2, IFN-γ, IL-10, and TGF-β1. SAC *in vitro* stimulated samples are used to quantify TNF-α and IL-12. Using ELISA kits, cytokine production, IL-2, IL-12, TNF-α, IFN-γ, and IL-10 levels are measured. Samples are acidified by 1-M HCl and measured by Quantikine antihuman TGF-h1 kit for detection of the TGF-h1 immunoreactive form.

5.2.7.4 IFN-γ Assay

Human myelomonocytic KG-1 cells (ATCCCCL246) are incubated with RPMI-1640 medium supplemented with 10% FCS, 100-µg/mL penicillin, and 100-µg/mL streptomycin at 37°C in air containing 5% CO_2. By expression of the corresponding cDNA in *E. coli* HuIL-18 and MuIL-18 are prepared and purified to homogeneity. Using Pfu DNA polymerase (at 95°C for 45s; at 72°C for 3.5min; 10 cycles and at 95°C for 45s; at 68°C for 3.5min; 35 cycles) MuIL-18R cDNA (1.7kbp) are amplified from murine liver RNA by RT–PCR and cloned into pCRScript Cam SK (+) to synthesize 5′-AGAGGAACCACCCACAACGATCCT-3′ and 5′-TGAATAGGCACACGCAT-XGACCTCT-3′ [112]. With the EF-1 promoter of pEF-BOS vector, the dihydrofolate reductase unit of pSV2dhfr (ATCC 37146) and the backbone of pRc/CMV vector pREF-XN is constructed. IL-18R cDNA is ligated into *Xho*I/*Not*I sites of the vector to form MuIL-18R expression vector pRcEFM18R. KG-1 cells (1×10^7) are washed twice with RPMI-1640 medium and transfected with 50mg of pRcEFM18R by electroporation. In the presence of 400-µg/mL G-418, the transformed cells are selected and cloned. The suspension of 2×10^6 cells, on which the receptor binding of ^{125}I-labeled MuIL-18 or HuIL-18 has been examined, in RPMI-1640 containing 0.1% NaN_3 and 100-mM HEPES (pH 7.2) is incubated at 4°C for 1h with approximately 4ng of ^{125}I-labeled MuIL-18 or HuIL-18. After the separation of unbound IL-18, the cell-bound ^{125}I count is determined. Subtracting the nonspecific binding measured from 3µg of unlabeled cognate ligand, the specific binding of IL-18 is obtained. To prepare mice serum containing endogenous MuIL-18, C57BL/6 mice are treated with 500µg of heat-killed *Propionibacterium acnes* for 1 week and challenged with 1µg of lipopolysaccharide for 2h to induce endotoxic shock. From

the heart, under proper anesthetization, blood samples are taken to prepare sera. The MuIL-18R-expressing KG-1 cells are washed and resuspended at 5×10^5 cells/mL with RPMI-1640 medium for 2 days. The cells are adjusted to 1×10^6 cells/mL with RPMI-1640 containing 10% FCS, to which the indicated amounts of MuIL-18, HuIL-18, or serum sample are added. One day later, the culture supernatants are recovered and the quantitative analysis of the produced IFN-γ is performed by ELISA. The culture supernatant is incubated with mAb-IFN-γ-15. The bound IFN-γ is further incubated with mAb-IFN-γ-6 and detected with hydrogen peroxide and o-phenylenediamine.

5.2.7.5 Anti-rHuEPO NAb Assay

32D-EPOR cells are incubated at 37°C in humidified atmospheric air containing 5% CO_2 with RPMI 1640 supplemented with 15% heat-inactivated FBS, 2-mM l-glutamine, and penicillin/streptomycin (1%, v/v) mixture. The EPO-dependent cells are incubated in RPMI 1640 supplemented with 10 U/mL of rHuEPO. Via two to three subcultures a week, cell densities are maintained between 3×10^4 and 1×10^6 cells/mL. Up to 30 days after thawing, the old cells in the cryopreserved cells are discarded and a vial of frozen cells is thawed and expanded in culture [113].

In the cell proliferation assay, 32D-EPOR cells are incubated overnight, harvested, and washed twice with RPMI 1640 lacking rHuEPO by centrifugation (200–300 g). The supernatant is discarded, the cell pellet is resuspended in RPMI 1640, and the suspention is recentrifuged. The formed cell pellet is resuspended in RPMI 1640 and adjusted to 5×10^5 cells/mL. Cells are incubated at 37°C (humidified atmospheric air containing 5% CO_2, without rHuEPO) for 16–24 h, centrifuged, resuspended in fresh RPMI 1640, and counted. Overall, 100 μL of 2×10^4 staged 32D-EPOR cells and 100 μL of prepared testing sample are incubated at 37°C for 44 h in humidified atmospheric air containing 5% CO_2. The solution of 2-μCi [methyl-3H] thymidine diluted in 50 μL of RPMI 1640 is added to each well and incubated for 4 h. The contents of the plate are harvested, 25 μL of scintillation fluid are added, and the cells are counted.

All assay controls are prepared in a mixture of 5% human serum and 15% pooled rat serum. In anti-rHuEPO NAb assay, the background control (N) consisting of cells only is prepared by mixing 40 μL of pooled human serum with 240 μL of RPMI 1640 and 120 μL of pooled rat serum. The maximum growth control (M) consisting of cells and 1-ng/mL rHuEPO is prepared by mixing 40 μL of pooled human serum with 120 μL of rHuEPO at 6.67-ng/ml, 120 μL of RPMI 1640 and 120 μL of pooled rat serum. The neutralizing antibody positive control (P) consisting of cells, 1-ng/mL rHuEPO and 500-ng/mL positive control antibody is prepared by mixing 120 μL of RPMI 1640 with 120 μL of pooled rat serum. Samples are prepared by mixing 40 μL of individual donor serum with 120 μL of rHuEPO at 6.67 ng/mL, 120 μL of RPMI 1640, and 120 μL of pooled rat serum. Before addition to the cells, all controls and samples are preincubated at room temperature for at least 30 min.

5.2.7.6 Radial Assay of Chemotaxis

From stock sorocarp cultures of *D. discoideum* grown on agar plates, spores from strain v12 are harvested and heat-shocked at 45°C for 30 min. The suspension of

the spores is mixed with a full loop of *E. coli* B/r, the 200-μL aliquots in new SM-agar plates are cultured at 22°C for 24 h, the cells are harvested and maintained vegetatively by shanking (200 rpm in Lpp medium, approximately 10^6 cells/mL), or the cells are starved by washing four times by centrifugation (3000 g, 30 s). The cells are shaken in 15-mM Tris-HCl (pH 7.0) for 2 h or 4 h; the latter is for routine chemotaxis assays. Chemotaxis of *D. discoideum* amoebae is performed on thin agar plates. Overall, 1 mL of 1.0% agarose in 15-mM Tris-HCl (pH 7.0) is added to each Petri plate and agitated to allow even spreading. The chemoattractants cAMP or folic acid are added to the agar with or without agonists before pouring plates. Chemotactically competent cells are centrifuged to form a viscous suspension and spotted on the agar plates. Each plate containing six aliquots of cells is covered, incubated at 22°C for 3 h, uncovered and placed on a heater to fix cells and dessicate the agar. As a measure of chemotactic efficiency, the initial spot diameters are subtracted from the diameters of visible rings or "halos" formed by outwardly migrating cells. During a period of 60 min with a playback time of 3 min, the individual halos on the agar plates are monitored. Proteins (20 μg/lane) are separated from whole cell lysates by polyacrylamide gel electrophoresis in 12% sodium dodecyl-sulphate polyacrylamide gels and transferred to nitrocellulose membranes in a mini-trans-blot cell using a buffer containing 25-mM Tris, 192-mM glycine (pH 8.3), and 20% methanol. Transfer is with 100 V for 40–60 min employing a frozen cooling unit. Using standard curves produced by running prestained Rainbow markers in parallel lanes, relative molecular weights are estimated. Nitrocellulose blots are blocked in 4% BSA at 4°C for 16 h, incubated for 1 h in 1/500 monoclonal anti-phosphotyrosine PT-66, and diluted by a 1/1000 dilution of peroxidase conjugated goat-antimouse IgG at room temperature for 1 h to detect the proteins containing phosphorylated tyrosine residues. Between each incubation, blots are washed three times for 5 min and immunoreactive bands are visualized using the chromogenic substrate diaminobenzidine HCl and 0.025% peroxide.

5.2.8 ESTROGEN ASSAY

After transfection, some cells become special fused cells such as the GAIA–DNA domain binding estrogen receptor yeast [114], the HELNα and HELNβ transfected cells [115], the yeast stably expresses human estrogen receptor β (hERβ) [116], the yeast stably expresses human estrogen receptor α (hERα), and enhanced green fluorescent protein (yEGFP) in response to estrogens α (hERα) [117]. With the special characteristics and high response to estrogen stimulation, the mentioned cells and related substances are used for bioassays.

5.2.8.1 Yeast Oestrogen Assay

The yeast, of which the steroid-binding domain is fused by GAL4-VP16, is incubated with SC-medium without histidine at 30°C and 130 rpm overnight. By adding DMSO up to a final concentration of 15% (v/v), stock cultures are prepared from exponentially growing cultures and stored in 0.5-mL aliquots at −80°C. Exponentially growing overnight, cultures are diluted with SC-medium to an OD_{600nm} of 0.75. To 10-mL aliquots 100 μL of DMSO (negative controls), 100 μL of 17β-estradiol in DMSO (positive controls), or 100 μL of test compound in DMSO are added, incubated at 30°C and 130 rpm for 2 h, diluted to five-fold volume and

determined to get OD_{600nm}. To 200 µL of the test culture, 600 µL of Z-buffer (60-mM $Na_2HPO_4 \cdot 7H_2O$, 40-mM $NaH_2PO_4 \cdot H_2O$, 10-mM KCI, 1-mM $MgSO_4 \cdot 7H_2O$, 35-mM β-mercaptoethanol), 20-µL SDS solution (3.5 mM), and 50 µL of chloroform are added, carefully mixed, and pre-incubated at 28°C for 5 min, and then 200 µL of o-nitrophenyl-3-D-galactopyranoside in Z-buffer (13.3 mM) are added to initiate the enzyme reaction. The cultures are incubated at 28°C until a significant yellow color develops. For 17β-estradiol-induced positive controls, the yellow color occurs within 20 min. For test chemical-induced assays, the yellow color occurs after 120 min. To the cultures, 500 µL of Na_2CO_3 (1 M) is added to stop the reaction, the cell debris is pelleted by centrifugation (25,500 g, 15 min), and the Ex_{420nm} of the supernatants is determined. The β-galactosidase activity of the test cultures is calculated according to u[µ mol/min] = Cs/t·V·ODs, wherein t = incubation time (min) of the enzyme reaction, V = volume (0.2 cm^3) of the used test culture aliquot, ODs = OD_{600nm} of test culture, Cs = concentration of o-nitrophenyl-β-D-galactopyranoside (µM) in the reaction supermatant calculated according to Cs(µM) = $10^6 \cdot [Exs\text{-}Ex_B]/\in_N \cdot d$, wherein Exs = Ex_{420nm} of the enzyme reaction supernatant of test compound, ExB = Ex_{420nm} of the enzyme reaction supernatant of the blank control, $\in_N = \in$ for o-nitrophenyl-β-D-galactopyranoside in the enzyme assay reaction mixture (4666 × 10^3 cm^2/mole), and d = diameter of the cuvette (1 cm). EC_{50} are calculated from dose response curves obtained by fitting the data by $Y = D + [A - D]/[1 + (C/X)^B]$, wherein X = estrogen concentration in the test, Y = β-galactosidase activity, B = relative slope of the middle region of the curve as estimated from a linear/log regression of the linear part of the dose response curve, C = estrogen concentration at half maximal response, and D = minimum β-galactosidase activity. The relative β-galactosidase induction factor defined as the ratio of β-galactosidase activity in a chemical sample and in the corresponding negative control is used for test chemical sample screening results.

5.2.8.2 HELN α and HELN β Transfected Cell Assay

After incubation with 30 mg of C18 Oasis HLB batch for 10 min, 800 mL of every patient's serum are desteroided and centrifuged (13,000 g, 10 min) to separate the supernatant. To this stripped serum, a known amount of estradiol is added to obtain a set of estradiol standards with concentrations from 10^{-9} to 10^{-4} mM, and incubated for 4 h at 37°C to permit an equilibrium bet-ween free estrogens and estrogens bound to sex hormone-binding globulin. HeLa cells transfected with ERE-β Glob-Luc-SVNeo and pSG5-Puro-hERα or β, so-called HELNα and HELNβ, are selected by geneticin and puromycin at 1 mg/mL and 0.5 µg/mL, respectively. Luminescent and inducible clones are identified using photon-counting cameras. HELN Erα is cultured in 150-cm^2 plastic flasks in DMEM without phenol red, supplemented with 5% dextran-coated and charcoal-treated FCS, 0.25-µg/mL puromycin, and 0.5-mg/mL geneticin. To the culture medium, the aromatase inhibitor aminogluthetimide (AG) is added at a concentration of 50 µM. The cells are seeded in 96-well plates (3 × 10^4 cells per well) in the presence of DMEM without phenol red, supplemented with 3% dextran-coated and charcoal-treated FCS, 50-µM AG, and incubated for 8 h at 37°C. Culture medium is replaced by 100 µL of DMEM without phenol red, supplemented with 50-µM AG, to which 20 µL of human serum in triplicate is added.

5.2.8.3 Luciferase Assay

The p403- and p405-GPD yeast expression vectors and the p406-CYC1 yeast expression vector are used to express the human estrogen receptor α and β and construct the reporter plasmid, respectively. On the isolated mRNA of T47D human breast cancer cells and intestinal Caco-2 cells, cDNA is synthesized. Using the T47D cDNA, marathon uterus cDNA, and the human intestine cDNA by PCRs, full-length human estrogen receptor β (ERβ) cDNA is obtained. To perform the first PCR, 34.2 μL of ultra-pure water, 5 μL of 25-mM $MgCl_2$, 5 μL of Expand HF 10 × concentrated buffer (without $MgCl_2$), 0.8 μL of 25-mM dNTP mix, 1 μL of the enzyme mixture, 2 μL of the different cDNAs, and 2 μL of a primer mixture containing 10 μM of each primer are pipetted into a thin-walled PCR tube and (1) denature template 3 min at 95°C, (2) denature template 30 s at 94°C, (3) anneal primers 1 min at 60°C, (4) elongation 2 min at 72°C, (5) go to step (2) and repeat 35 times, (6) elongation 7 min at 72°C, and (7) for over 10°C. The second PCR is performed with the same conditions, but 2 μL of the first PCR mixture is used instead of 2 μL of the different cDNAs. The 5′- and 3′-primer, 5′-CGTCTAGAGCT GTTATCTCAAGACATGGATATAA-3′ and 5′-TAGGATCCGTCACTGAGA CTGTGGGTTCTG-3′, contains a restriction site for *Xba*I just before the ATG start codon and for *Bam*HI just after the TGA stop codon, respectively. The full-length ERβ PCR product is isolated and ligated into a pGEM-T Easy Vector. The uterus/intestine human ERβ cDNA clone that fully corresponded to the ERβ sequence is cut out of the pGEM-T Easy plasmid with *Xba*I and *Bam*HI and cloned into the corresponding *Xba*I–*Bam*HI site of the p405-GPD-ERβ vector, which is used to transform Epicurian Coli XL-2 Blue Cells.

Yeast K20 is transfected with the p406-ERE2s2-CYC1-yEGFP reporter vector and integrated at the chromosomal location of the Uracil gene via homologous recombination to construct yeast hERα and hERβ cytosensors. The transformants are grown on MM/LH plates using PCR and Southern blot hybridization to select clones, in which the integration has occurred at the desired URA3 site with only a single copy of p406-ERE2s2-CYC1-yEGFP. This strain is transformed with the p403-GPD-Erα and the p405-GPD-ERβ, or both expression vectors and transformants are grown on MM/L, MM/H, or MM plates, respectively.

The plate with selective MM/L, MM/H, or MM medium is inoculated with −80°C stock yeast ERα, ERβ, or ERα/β cytosensor (20% glycerol, v/v), respectively; incubated at 30°C for 24–48 h; and stored at 4°C. The day before the assay, a single colony of the yeast cytosensor is inoculated with 10 mL of the corresponding selective medium overnight at 30°C with vigorous orbital shaking at 225 g. At the late log phase, the yeast ERα, ERβ, and ERα/β cytosensor culture is diluted (1 : 10) in MM/L, (1 : 20) in MM/H, and (1 : 20) in MM, respectively. This minimal medium consists of a yeast nitrogen base without amino acids or ammonium sulphate (1.7 g/L), dextrose (20 g/L), and ammonium sulphate (5 g/L). The MM/L and MM/H medium are supplemented with L-leucine (60 mg/L) or L-histidine (2 mg/L), respectively.

A total of 200-μL aliquots of the yeast culture are pipetted into each well of 96 well plates, and then 1 μL of ethanol or DMSO stock solution of test chemical is added to result in 0.5% final concentration. The plates are included for 4 h and 24 h, fluorescence at 485 nm and emission at 530 nm are measured directly, and the OD

of the yeast culture at 630 nm is determined to check the toxicity of test chemical for yeast.

5.2.8.4 Green Fluorescent Protein Expression Assay

Aliquots of 2 mL of blank calf urine and 17β-estradiol (E2β, 1 ng/mL), diethylstilbestrol (DES, 1 ng/mL) and 17α-ethynylestradiol (EE2, 1 ng/mL), α-zearalanol (30 or 50 ng/mL) and mestranol (10 ng/mL), and spiked calf urine samples are adjusted to pH 4.8 and 20 μL of β-glucuronidase/arylsulfatase (3 U/mL) are added. The samples are deconjugated by enzyme at 37°C overnight, treated with 2 mL of 0.25-M sodium acetate buffer (pH 4.8) and subjected to solid phase extraction (SPE) on a C18 column conditioned previously with 2.5 mL of methanol and 2.5 mL of sodium acetate buffer. The column is successively washed with 1.5 mL of 10% (w/v) sodium carbonate solution, 3.0 mL of water, 1.5 mL of sodium acetate buffer (pH 4.8), 3.0 mL of water, and 2 mL of methanol/water (50/50 v/v). The column is air-dried and eluted with 4 mL of acetonitrile. The eluate is applied to an NH_2-column conditioned previously with 3.0 mL of acetonitrile. The acetonitrile eluate is evaporated to 2 mL by nitrogen gas stream, of which a 100-μL part (equivalent to 100-μL urine) is transferred to a 96-well plate and mixed with 50 μL of water and 2 μL of DMSO. The plate is dried overnight in a fume cupboard to remove the acetonitrile and screened on estrogenic activities with the yeast estrogen bioassay. In the same way, a reagent blank is prepared, using 2 mL of the 0.25-M sodium acetate buffer pH 4.8 instead of urine.

The yeast cytosensor (20% glycerol v/v) expressing the human estrogen receptor α (hERα) and yEGFP in response to estrogens is incubated in an agar plate containing the selective MM/L medium at 30°C for 24–48 h and then stored at 4°C. The day before the assay, a single colony of the yeast cytosensor is inoculated in 10 mL of selective MM/L medium overnight at 30°C with vigorous orbital shaking at 225 rpm. At the late log phase, the yeast ERα cytosensor is diluted in MM/L, giving an OD at 604 nm in the range of 0.07–0.13. For exposure in 96-well plates, aliquots of 200 μL of this diluted yeast culture are pipetted into each well, already containing the extracts of the urine samples. A E2β dose-response curve is included in each exposure experiment. Aliquots of 200 μL of the diluted yeast culture are pipetted into each well of a 96-well plate and exposed to different doses of E2βs performed through the addition of 2 μL of E2β stock solutions in DMSO. Each urine sample extract and each E2β stock is assayed. Exposure is performed for 0 h and 24 h. Fluorescence at these time intervals is measured directly using excitation at 485 nm and measuring emission at 530 nm. The densities of the yeast culture at these time intervals are also determined by measuring the OD at 630 nm to check whether a urine sample is toxic for yeast.

In the determination of the decision limit (CCα) and detection capability (CCβ) of the yeast estrogen bioassay, extracts of 20 blank calf urine, 20 spiked calf urine samples (E2β, DES and EE2 at 1 ng/mL, α-zearalanol at 30 or 50 ng/mL, and mestranol at 10 ng/mL), and a reagent blank are analyzed. After 24 h of exposure, the obtained fluorescence signals of the 20 blank urine samples, the 20 spiked urine samples, and a reagent blank are corrected for the signals obtained at 0 h (t_{24}–t_0). On three different days, the extracts of the blank urines and their corresponding spikes are prepared and analyzed in the yeast estrogen bioassay in three separate

exposures. Within a time period of 10 days, these three sample treatments and exposures are performed. In another experiment, extracts of 20 blank urines and spikes of 50-ng zearalanol per mL urine are prepared in one day and are analyzed in the yeast estrogen bioassay in one exposure. In the context of EC Decision 2002/657, the mean signal of 20 blank calf urine samples plus 2.33 times the corresponding standard deviation is defined as the decision limit CCα (α = 1%), and the decision limit CCα plus 1.64 times the standard deviation of the signal of the spiked calf urine sample is defined as the detection capability CCβ (β = 5%).

In the determination of the specificity of the yeast estrogen bioassay, three blank calf urine samples are spiked with a high dose of testosterone or progesterone (1000 ng/mL) and extracts are analyzed. In the determination of interference, these blank calf urine samples are spiked with a high dose of either testosterone or progesterone in combination with a low dose of estrogens (E2β, DES, and EE2 at 1 ng/mL, α-zearalanol at 50 ng/mL, and mestranol at 10 ng/mL).

5.2.9 ANTIMALARIAL ASSAY

The tremendous progress in the biology and the biochemistry of malaria parasites has led to the identification of drug targets that are both parasite specific and essential for parasite growth and survival, and some of them are now exploited in the mechanisms-based assays of various screening programs and determination of antimalarials' concentration such as plasmodium falciparum and murine P388 leukemia cell assay [118], histidine-rich protein II assay [119], anti-plasmodium activity assay [120], survival of Anopheles gambiae assay [121], chloroquine plus doxycycline assay[122], and plasmodium falciparum clone and dihydroartemisinin assay [123].

5.2.9.1 Plasmodium Falciparum and Murine P388 Leukemia Cell Assay

The required quantity of *P. falciparum* parasites maintained in a complete medium (RPMI-1640, 25-mM HEPES, 25-mM $NaHCO_3$, and 10% pooled human serum, with uninfected human red blood cells at 2.5% haematocrit) is introduced into flat-bottomed 96-well plates. The cell suspension (1% parasitaemia) is added to the plates (0.2 mL/well), which contains test compound in triplicate alongside untreated controls. The plates are shaken vigorously using a microculture plate shaker, and they are incubated at 37°C for 18 h under microaerophilic conditions [124]. To each well, tritiating hypoxanthine with a specific activity of 14.1 Ci/mmol is added (0.5 µCi/well) and incubated at 37°C for another 24 h. The contents of the well are frozen at −30°C, unfrozen at 50°C, filtrated, and washed several times with water. The disks are dried and added to toluene scintillator in vials, and the radioactivity incorporated into parasites is estimated.

Test compounds inhibiting 75% or more of the parasite growth are systematically submitted to cytotoxicity tests. Murine P388 leukemia cells grown in RPMI 1640 medium containing 0.01-nM β-mercaptoethanol, 10-mM L-glutamine, 100-U/mL G-penicillin, 100-µg/mL streptomycin, 50-µg/mL gentamycin, and 50-µg/mL nystatine, supplemented with 10% fetal calf serum, are incubated in humidified atmospheric air containing 5% CO_2 at 37°C. The inoculum seed at 10^4

cells/mL (0.1 mL/well) is transferred into flat-bottomed 96-well plates containing serial concentrations of test compound, and the plates are incubated in the required atmosphere at 37°C for 72 h. Thereafter, cells are incubated at 37°C with a 0.02% solution of neutral red in 1/9 methanol/water (0.1 mL/well) for 1 h, washed with 1N PBS, and lyzed with 1% SDS. After a brief agitation, the plates are read at 540 nm to measure the absorbance of the extracted dye, and cell viability is expressed as the percentage of cells incorporating dye relative to the untreated controls and IC_{50} values are determined by the linear regression method.

5.2.9.2 Histidine-Rich Protein II Assay

The serial dilutions of complement-inactivated plasma samples, which are from uncomplicated falciparum malaria patients and a healthy volunteer treated with oral sodium artesunate (100 mg followed by 50 mg orally every 12 h for 5 days), are applied in two columns to 96-well microculture plates at 50 µL/well. The serial dilutions of spiked plasma are applied in two columns and added to each plate as controls. On each 96-well plate, five unknown samples plus the controls are tested; in addition, one plate with six serial dilutions of known drug concentrations covering the whole test range is also tested. According to the literature, the culture and ELISA procedures are performed [125]. A total of 175-µL aliquots of the dilutions (0.1% parasite density, 1.7% hematocrit) of synchronized parasitized (clone W_2) blood samples from continuous culture are added to the plates (resulting in a total of 225 µL/well), with the frozen mixture of 1.05 mL of the remaining cell medium and 0.3 mL of drug-free plasma per plate as negative controls. Before being frozen-thawed, the plates are incubated at 37°C for 72 h in a candle jar or gas mixture (5% CO_2, 5% O_2, 90% N_2).

5.2.9.3 Antimalarial Activity Assay

The chloroquine resistant strain FcB1 of *P. falciparum* (50% inhibitory concentration [IC_{50}] of chloroquine = 62 ng/mL) maintained continuously in culture on human erythrocytes is used for the evaluation of antimalarial activities of test compounds [126]. The semiautomated microdilution technique [127] is modified to determine the *in vitro* antiplasmodial activity of test compounds. The serial medium dilutions of the stock solutions of test compounds in DMSO 10 mg/mL, of which the concentration never exceeds 0.1% and does not inhibit the parasite growth, are incubated with asynchronous parasite cultures (0.5% parasitemia and 1% final hematocrit) on 96-well plates at 37°C for 24 h and treated with [^{3}H] hypoxanthine (0.5 µCi/well) for 24 h. By comparison of the radioactivity incorporated into the treated culture with that in the control culture maintained on the same plate, the growth inhibition concentration for each test compound is defined. From the drug concentration-response curve, the IC_{50} is obtained and expressed as the mean determined from three independent experiments.

5.2.9.4 Survival of *Anopheles Gambiae* Assay

Adults of laboratory-reared *An. gambiae* mosquitoes (from a colony established from wild gravid females, all mosquito life stages are maintained under semi-field conditions) are given 6% glucose solution on filter-paper wicks, water, and routine

human bloodmeals three times per week. Three days after each bloodmeal inside the cages, which are kept in screen houses under ambient conditions, oviposition cups are used to collect eggs on the following day. Under semi-field conditions, the larvae for both the colony and the experiments are maintained on fish food and the plastic pans (25 × 20 × 14 cm) are filled with fresh water [128].

In 30-cm cubic metal frame cages covered with mesh netting, approximately 100 pupae/cage and the test compound are for direct observation. *An. gambiae* mosquitoes are allowed to emerge, and evening observations of test compound feeding are conducted from 20:00 to 22:00 h, for which at intervals of 30 min, a flashlight is used. On a second night of observation, a mosquito net is placed over *Ricinus communis* in a screenhouse, under which a cup of water containing approximately 500 pupae is placed and emerging adults are allowed to feed on the test compound for 24 h. From 20:00 to 22:00 h in intervals of 30 min, on the following night, mosquitoes are observed until they are observed probing or feeding on the test compound.

For survival assay, mosquitoes are divided into regime groups. From the main mosquito colony, approximately 100 pupae per regime are harvested, transferred to plastic cups, and placed in cages and held in a screenhouse under ambient conditions. Each cage of mosquitoes has access to test compound sources; one group of mosquitoes has access to a cotton pad moistened with distilled water, representing negative controls; and another group of mosquitoes with neither test compound source nor water is used as an additional negative control. Dead mosquitoes are removed at 4-h intervals from 7:00 to 23:00 h until all die.

5.2.9.5 Chloroquine Assay

The blood samples (10 mL) from healthy volunteers who are on chloroquine (2 × 150-mg base weekly) and doxycycline (50 mg or 100 mg daily) malaria prophylaxis are centrifuged (1200 g, 10 min), and the plasma is separated and stored at –20°C. The chloroquine-sensitive FC27 strain of *P. falciparum* is used for the determination of antimalarial activity of each plasma sample [129]. On microculture plates, the plasma samples are diluted twofold with drug-free serum and inoculated with a suspension of parasitized erthrocytes in culture medium. The drug susceptibility and minimum concentration of spiked drug that inhibits parasites, relative to control, from developing to schizonts is recorded. The maximum inhibitory dilution (MID) of the volunteers' samples containing a choroquine concentration and the minimum inhibitory concentration (MIC) observed in the sensitivity test are recorded. The chloroquine equivalent concentration in the prediluted volunteers' specimen is estimated by multiplying the MID by the MIC.

5.2.9.6 Plasmodium Falciparum Clone and Dihydroartemisinin (DHA) Assay

By centrifugation for 5 s, 50 μL of Affigel protein A (binding capacity of 20 mg of purified human immunoglobulin G[IgG]/mg of gel) is washed twice with PBS (pH 7.2, 50 μL), and the RPMI 1640 medium (50 μL) that is supplemented with 5.94-g/L HEPES and 2.1-g/L sodium bicarbonate, centrifuged to discarde the supernatant, and Affigel protein A gel is incubated with the plasma and serum (250 μL) spiked with dihydroartemisinin (DHA) or plasma from patients at room temperature for

30 min [130]. The stock solution of DHA in 70% ethanol (1 mg/mL) is kept at −10°C for up to 1 month before use, which is further diluted in plasma or serum to give a working concentration (1.25 to 100 ng/mL).

Affigel protein A-treated plasma (100 µL) and heat-inactivated serum (50 µL/well) are transferred to row A and B of a flat-bottom plate, respectively. Using the heat-inactivated serum added through G into row B as the diluent for plasma or serum containing DHA, twofold serial dilutions are prepared. To row H, 50 µL of heat-inactivated control plasma or serum is added for parasitizing and nonparasitizing erythrocyte controls. To all wells for rows A to G and eight wells for row H, the suspension of 175 µL of malaria parasite-infected erythrocytes (W2 clone; 0.5% parasitemia with 80% young rings at a 1.7% hematocrit) is added. To the remaining four wells of row H for nonparasitized controls, the similar suspension of uninfected erythrocytes is added. The microtiter plates are incubated at 37°C for 24 h and treated with 1 Ci/mmol [^{3}H] hypoxanthine by the addition of 25 µL of 0.5 µCi isotope solution to each well. The microtiter plates are incubated for another 18 to 20 h. Harvesting the contents of the plates, the particulate material of the water-lysed cell suspension is collected on glass-fiber filter paper by filtration, and the filter paper is dried in an oven and placed in a plastic bag, to which 10 mL of scintillation fluid is added and the plastic bag is then sealed. By counting in a liquid scintillation counter, the level of incorporation of [^{3}H] hypoxanthine by the malaria parasites is determined.

Fresh whole blood is collected to heparinized tubes, and the plasma and buffy coat are removed, and the erythrocytes are lysed and serially diluted (2- to 64-fold) with sterile water, of which 50-µL aliquots are diluted in 250 µL of plasma or medium spiked with DHA to give a final concentration of 50 ng/mL and a range of hemoglobin concentrations from 1.5 to 0.05 g%. The effect of hemolysate in both plasma and culture medium (RPMI 1640 medium with 15% heat-inactivated human serum) on the detection of DHA activity is examined. The final concentration of plasma and serum in each well is 30% and 15%, respectively, which is similar to that in the normal drug susceptibility test. In addition to testing hemolysates of normal erythrocytes, the plasma samples collected from patients with severe falciparum malaria before treatment with any antimalarial drugs can also be spiked with 50 ng of DHA/mL and subjected to the same bioassay.

5.2.10 BLOOD PRESSURE-RELATED ASSAY

Blood pressure can be regulated by receptor, enzyme, endogerous substance, and cell, such as bradykinin B2-receptor, ACE, 5-Hydroxytryptamine, and endothelia cell. Based on these facts, the human plasma assay [131], pulmonary hypertension assay [132], coronary arteries (CA) constriction assay [133], MCAO and HSPG assay [134], and temperature assay in awake subjects [135] are established.

5.2.10.1 Human Plasma Assay

The solution of test peptide is injected (i.v.) into adult male Wistar rats (housed in pairs, under a 12 : 12 h light/dark cycle, 0.4% NaCl rat chow, and water available *ad libitum*, after 3–5 days of adaptation to the facility, about 300 g) at a proper dose.

The inactin (100 mg/kg, i.p.; sodium ethyl-(1-methyl-propyl)-malonylthio-urea) anesthetized rats are treated with atropine (2.4 mg/kg, s.c.), and their ganglions are blockaded with pentolinium (19.2 mg/kg, s.c.). Overall, 10-mg/kg captopril is administered i.v. acutely to the rats in the captopril group, and it inhibits fully the pressor effect of 60-ng/kg angiotensin I.

To assist ventilation, the trachea is intubated and both vagi are severed to block reflex bradycardia. Into the right femoral vein and carotid artery, catheters are inserted for the injection of test compound and other agonists and antagonists, and for monitoring arterial blood pressure and heart rate and for blood sampling, respectively [136, 137], and blood pressure is monitored.

Responses, in terms of the increases in systolic (SBP) and diastolic (DBP) blood pressures, to test peptide and bradykinin are determined. After ganglion blockade with pentolinium (group GB) without or with added captopril (group GB+Cap), heart rate and plasma adrenaline and noradrenaline concentrations are determined. In some cases, the rats are not subjected to ganglion blockade and served as controls for animals in the GB group (control group).

To evaluate the contribution of bradykinin B2-receptor-mediated mechanisms, the selective bradykinin B2-receptor antagonist, HOE-140, is given to ganglion-blocked, the rats are captopril treated, and the increases in SBP, DBP, heart rate, and plasma adrenaline/noradrenaline induced by test peptide and bradykinin (group GB+Cap+HOE) are observed. To evaluate the contribution of AT1-receptor-mediated mechanisms, the selective AT1 receptor antagonist, losartan, is given to group GB rats before and after treatment with captopril (1 mg/kg, i.v.) and the increases in SBP, DBP, heart rate, and plasma adrenaline/noradrenaline induced by test peptide are observed.

For determining plasma adrenaline and noradrenaline arterially approximately 1 mL of blood is withdrawn via the carotid cannula at baseline (before injection of test peptide and bradykinin), at the peak of the SBP response, and after recovery from the response [138, 139]. Before each withdrawal, the rat is given a transfusion of approximately 1 mL of blood from a similarly prepared donor rat. The SBP peak is observed at 2–3 min after the injection of test peptide and at 1–2 min after the injection of bradykinin; blood sampling coincides with these intervals. Using HPLC and fluorimetric detection, plasma catecholamines are determined [140].

5.2.10.2 Pulmonary Hypertension Assay

The chest cavity of a mouse (10–20 weeks old, 22–30 g) anesthetized by pentobarbital sodium (80 mg/kg, i.p.) is opened, and the lungs are removed rapidly and placed in Krebs–Ringer bicarbonate solution (KRBS) containing 118.3-mM NaCl, 4.7-mM KCl, 1.2-mM $MgSO_4$, 1.2-mM KH_2PO_4, 2.5-mM $CaCl_2$, 25.0-mM Na_2CO_3, and 10.0-mM glucose, bubbled with 21% O_2. From the intrapulmonary artery (third to fourth generation, PA), rings (50–100 μm internal diameter, 2–3 mm long) are isolated using a dissection microscope. PA rings are mounted as ring preparations by threading two steel wires into the lumen and securing the wires to two supports, and they are placed in a small vessel wire myograph chamber. The support is attached to a micrometer for the control of ring circumference and to a force transducer for measurement of isometric tension, respectively. After removal of endothelial cells by gently rubbing the intraluminal surface with a steel wire,

some vessels are successively perfused with 2-mL air bubbles and 2-mL of KRBS (perfusion pressure < 5 mm Hg), before being mounted in the chamber. In the chamber filled with KRBS (pH 7.35–7.45), bubbled with 21% O_2–5% CO_2–balance N_2, the whole preparation is kept at 37°C. To control oxygen tension over the superfusate, Plexiglas is used as a cover over the chamber. The temperature and PA tension are recorded. At initial tension of 0 mN (1 g = 4.905 mN), isolated murine PA rings in the chamber are allowed to equilibrate for 10–15 min, which are increased to 5 mN in 2.5-mN steps at 4- to 5-min intervals and held constant thereafter. Through preliminary experiments, the resting tension for maximal constrictor response is optimized, in which the resting tension levels of 2.5, 5, and 7.5 mN are compared. In the evaluation of vascular viability, after the treatment of PA with 60-mM KCl, the tension is determined. The PA is washed extensively with KRBS, successively exposed to U-46619 (0.01 μM, thromboxane A_2 agonist) and 1-μM Ach, the resulting tension is recorded and stabilized for 5–10 min, and the agonists are washed out of the myograph chamber with KRBS.

Murine PA is isolated, placed in a confocal pressure myograph chamber, cannulated at both ends with glass micropipettes, and secured with a 12-0 nylon monofilament suture. To control transmural pressure, both cannulas are connected to a reservoir that can be raised or loared. In the chamber, PA is superfused at 37°C, constantly with KRBS, and gassed with 21%O_2–5%CO_2–balance N_2. To control oxygen tension over the superfusate, Plexiglas is used as a cover over the chamber. To the chamber, 0.1-mM dihydroethidum (DHE) is added, in which murine PA is incubated at 37°C for 45 min and then washed for 30 min. The reaction of ntracellular DHE and ROS produces a fluorescent oxidized product [141, 142] and PA images are scanned (480-nm-line argon laser, fluorescence 620 nm). Superoxide anion levels in isolated murine PA are measured by a lucigenin-enhanced chemiluminescence technique [143, 144] and scintillation counter, using a solution of 5-μM lucigenin in Krebs–HEPES buffer (10.0-mM HEPES acid, 135.3-mM NaCl, 4.7-mM KCl, 1.2-mM $MgSO_4$, 1.2-mM KH_2PO_4, 1.8-mM $CaCl_2$, 0.026-mM Na-EDTA, and 11.1-mM glucose), 1-mL total volume, after background chemiluminescence activity has stabilized for 5 min.

5.2.10.3 Coronary Arteries (CA) Constriction Assay

The left main coronary arteries (CA, 70–90 μm in diameter, 1-mm length) of a mouse are placed into a microvascular chamber, cannulated at both ends with glass micropipettes, and pressurized. By gently rubbing the intraluminal surface with a steel wire, the endothelial cells of some vessels are removed. The vascular intraluminal pressure (Ptm) is measured by using a pressure transducer positioned at the level of vessel lumen. The vessels in the chamber are superfused constantly with recirculating Krebs–Ringer bicarbonate solution containing 118.3-mM NaCl, 4.7-mM KCl, 1.2-mM $MgSO_4$, 1.2-mM KH_2PO_4, 2.5-mM $CaCl_2$, 25.0-mM $NaHCO_3$, and 11.1-mM glucose, which is gassed with 16% O_2, 5% CO_2, and balance N_2 (pH 7.35–7.45), and maintained at 37°C. To control oxygen tension over the superfusate the chamber is covered by Plexiglas, through which port an oxygen electrode is passed into the superfusate and positioned near the vessel to provide continuous measurement of oxygen tension. The vascular intraluminal diameter (ID) is measured continuously. The oxygen tension, vascular ID, and Ptm are recorded. The

isolated CA in the chamber is allowed to equilibrate 30 min at a Ptm of 10 mm Hg, which is increased to 60 mm Hg in 10-mm Hg steps at 5–7-min intervals and held constant thereafter. When Ptm is increased to 60 mm Hg (time 0), the ID is recorded (appointed to ID60, namely ID at Ptm = 60 mm Hg) and the measurement is continued throughout the experiment.

The superoxide anions produced in isolated murine CA are measured using a lucigenin (bis-*N*-methyacidinium nitrate)-enhanced chemiluminescence technique. After background has stabilized chemiluminescence activity for 5 min, CA is placed in the chemiluminometer containing 1 mL of 5-μM lucigenin buffer solution, photon emission is recorded continuously, and the chemiluminescence signal is recorded as relative light units per second (RLU/s).

5.2.10.4 Middle Cerebral Artery Occlusion (MCAO) Assay and Vascular Heparan Sulfate Proteoglycans (HSPG) Perlecan Assay

Male baboons are randomly divided into treatment and control groups. In the treatment groups the animals undergo MCAO for 1 h or 2 h, or 3 h MCAO with subsequent reperfusion for 1 h or 4 h, or 1.5 h MCAO with 24 h reperfusion. In the control groups, the animals do not undergo any preparation procedure or suffer from MCAO at surgical implantation and has sustained hemiparesis for 7 days. The animals are transcardially perfused with isosmotic heparinized perfusate, and their brain tissues are removed under thiopental Na and prepared for frozen and paraffin sections [145, 146]. The samples of normal and 50 μL of ischemic brain tissue or 100 μL of purified reagents are added to the recipient tissues consisting of unfixed 10-μm-thick normal basal ganglia sections mounted on microscope slides.

When proteases are added to the normal recipient tissues, PBS (pH 7.0) is the incubation buffer for type-7 bacterial collagenase. The solution of matrix metalloproteinases (MMPs) and urokinase/plasminogen in a buffer containing 90-mM NaCl, 5-mM KCl, 1.5-mM $MgCl_2$, 23-mM Na gluconate, 27-mM NaAc, 10-mM $CaCl_2$, and 40-mM $ZnCl_2$ (pH 7.4) is prepared. The solution of cathepsin B and L in 200-mM NaAc containing 8-mM dithiothreitol, 1-mM EDTA, and 2.7-mM L-cysteine (pH 6.0) is prepared. The mixture of 5-U/mL plasminogen and 5-U/mL uPA is incubated at 37°C for 1 h; 1-μg/mL Pro-MMP-2 or 1-μg/mL pro-MMP-9 is added and incubated for 1 h. The recipient sections are incubated with 100 μL of each mixture or buffer alone at 37°C for 5 h (collagenase) or 18 h (MMPs and cathepsins) and washed with PBS and fixed.

From approximately 1.0-cm × 1.0-cm × 10-μm frozen sections, donor samples are derived. By centrifugation (300 g, 30 s) and repeated gentle pipetting, the mixture of 10 consecutive 10-μm sections of ischemic or normal basal ganglia is prepared. Overall, 50 μL of sample or PBS is added to the recipient sections, the mixture is incubated at 37°C for 18 h, and the recipient sections are washed with PBS and fixed in acetone or paraformaldehyde (PFA).

In the development of the specific antigens, the immunoperoxidase methods are used [147]. At 4°C, the overnight incubation of acetone-fixed frozen sections in the presence of the primary antibody is followed by developing immunoperoxidase with 3,3′-diaminobenzidine tetrahydrochloride. At 4°C, the overnight deparaffination of acetone-fixed frozen sections in the presence of the primary antibody is also followed by developing immunoperoxidase with 3,3′-diaminobenzidine

tetrahydrochloride. Incorporating dUTP into nuclear DNA is used as the evidence of nuclear DNA scission/repair, and at 2h, MCAO defines the ischemic core and peripheral regions of cellular neuronal injury. PFA-fixed cryosections are subject to the DNA polymerase I method [148]. All ischemic samples include ischemic core and ischemic peripheral regions. In the measurement of MMP-related activities, Gelatin zymography is performed with a modification to increase sensitivity [149]. Protease activities are identified by incubation of the gels in buffer containing GM6001 or APMSF.

5.2.10.5 Temperature Assay in Awake Subjects

The male SD rats (250–325g) are caused reversible ischemia with the intraluminal filament occlusion of the middle cerebral artery (MCA) and maintained anesthesia with 2% halothane and mixed gas of nitrous oxide and oxygen (60:40) by face mask [150]. To expose the left carotid artery, a midline neck incision is made. The external carotid and pterygopalatine arteries are ligated with 5-0 silk. In the arterial wall, an incision is made. From the bifurcation of external and internal carotid arteries, a 4-0 heat blunted nylon suture of 18mm is advanced. This distance reliably produces blockage of the origin of the MCA. The duration of occlusion for individual rats is varied to generate a range of ischemia durations for each experimental group. During surgery, the temporalis and brain temperature are monitored and maintained.

During the period (4–5h) of post-anesthetic recovery, the awake rats are kept on a pad maintained at 37.5°C. To verify the effect of this procedure on brain temperature, an indwelling radio telemetry thermister is implanted into the rat of the nonischemic group. After induction of anesthesia, the rat is placed in a stereotaxic head frame. A thermister probe is placed in the left parietal cortex (3mm deep to dura and 1mm anterior, 3mm lateral to bregma). To secure the probe to the skull, a plastic cap is fitted using methylmethacrylate [151]. After full recovery from the anesthesia, telemetered brain temperature is measured every 15min. Temperatures are measured every 5min for 24h during a baseline period and 6h after drug administration. After a drug treatment, some animals are placed on a heating pad for 2h and their temperature is measured every 15min. At 48h and 72h, the behavior of the rats is evaluated and classified to normal/abnormal according to a modified rodent examination scale [152]. All obtundation/reduced exploration, forepaw retraction on tail lifting, asymmetric forepaw grasp, axial twist, forced circling, or death are defined as abnormal.

To correctly position the filament, 0.2mL of 2% Evan's Blue in saline is injected into each rat via tail vein and circulated for 30 to 60min, after which the rat is perfused transcardially with 100-mL normal saline, and the brain is removed and immediately examined. Each day, two rats of the control group and four or five rats of the drug treatment group are injected test compound dissolved in saline via tail vein at 30, 60, 75, 120, 240, or 360min after initiating occlusion to assess therapeutic efficacy.

To determine the effects of the test compound on blood gases, heart rate, and arterial blood pressure in separate groups, physiological determinations are performed. To observe the interaction between test compound and anesthesia, the determinations in awake or in anesthetized rats are performed. The ventral tail

artery is cannulated with PE50 tubing for recording the arterial pressures and sampling arterial blood. Test compound is administered after the rat is stable for 30 min with no further adjustments needed to maintain homeostasis under 75–90 mmHg steady-state mean arterial pressure (MAP) and minimal halothane. To obtain similar data from awake subject, tail artery catheters are implanted under halothane inhaled anesthesia. After implantation, the rat is allowed to recover and is lightly restrained. One hour after stopping the anesthesia, the cannula is attached to the transducer and vital signs are recorded for a 30-min baseline period. After the subject is shown to be stable for 30 min, the test compound is given. Blood pressures and blood gases are recorded every 10 min for 1 h and then hourly.

5.3.1 INTRODUCTION

Current guidance documents for the assessment of analytes and their metabolites in biological fluids are focused primarily on the quantification of small molecules using chromatographic and mass spectrometry platforms [1–7]. Specific recommendations coming out of these guidances fall short in the immunoassay realm. The antibody binding of analytes directly from biological fluids confers a practicality and specificity unique to these assays. These assays are typically nonlinear and experience specific issues associated with the protein matrix, e.g., the presence of endogenous materials, to name just one. Until the authorities propose a guideline targeted at best practices in developing and validating ligand binding assays (antibody-based immunoassays) to support pharmacokinetics/toxicokinetics (PK/TK), the following recommendations, based on the paper generated by a 10-member panel from Biotech, Pharma, and CROs [8], and supported by several previous publications on the topic [9, 10], are proposed.

Assay development and implementation are dynamic processes. The life-cycle steps of development, validation, and in-study assay monitoring can be reassessed throughout the process as the analyst benefits from the experience of extended use, adds stability data, or updates current precision and accuracy data.

During early immunoassay development, it is important to assess the "intended use" of the assay. When the intended use is to support pharmacokinetics in either nonclinical PK/TK or clinical bioequivalence (BE) studies, developing a validatable assay is of utmost importance. A well-thought-out validation plan and fully documented assay methods and results that support the validation are crucial. To withstand the scrutiny of the authorities, and to guarantee the optimal method is applied to your drug development process, the following parameters should be assessed critically, validated to specific criteria, and fully documented.

5.3.2 ASSESSMENT PARAMETERS

The goal of the development phase for immunoassays is to establish a method that can consistently produce a reliable result culminating in a validation plan with established target acceptance criteria for accuracy and precision. The following recommended parameters are assessed critically during early development, evaluated in late development, and finally, confirmed during validation.

5.3.2.1 Reference Material

Inherent to macromolecules is the associated variability (i.e., glycosylation and deamidation) of the material from different preparations. Therefore, it is not usually feasible to obtain a "reference standard" for a macromolecule drug for use in bioanalysis. Typically, what is obtained is a well-characterized product. Therefore, it is important to clearly state the source of the material and to refer to any documentation describing characteristics of that material. Whenever possible, the standards, the validation samples, and quality control (QC) samples should be prepared from separate vials of the same source material. In the case of lyophilized material, it is preferred to reconstitute two separate vials to prepare standards and QCs. In

circumstances of limited availability of reference material (e.g., drug interaction studies where the pure standard is not available except from a limited source of commercial kits), standards and QC samples can be prepared from single aliquots after checking the comparability between lots or other commercial sources. In any circumstance, the lot numbers, batch numbers, and supporting documentation should be carefully monitored. This is a critical parameter that should be evaluated during method transfers and cross-validation studies.

5.3.2.2 Assay Format/Reagent Selection

Assay formats more recently have been defined as much by the platform (ELISA, RIA, Bioveris, Luminex) as by the type of immunoassay (direct or indirect binding, sandwich, competition or inhibition). Considering several different formats before selecting one is optimal, if time allows, because there are pros and cons to each format. Solid phase formats include glass, treated plastics, and coated plates (e.g., streptavidin). As antibody binding to the coated surface is highly dependent on pH, buffer content, salt concentration, detergents, nonspecific carrier protein, temperature, and shaking, any relevant conditions should be tested during the development of an immunoassay. When solid phase formats prove difficult, solution phase binding, for instance using coated beads, can result in a practical and sensitive assay.

The antibody or pair of antibodies selected for the assay format is the primary critical reagent for an immunoassay because it will ultimately define the specificity and sensitivity of the assay. Therefore, whenever possible, as many antibodies or pairs should be tested hand-in-hand with the selection of the assay format before moving into further development. This may include whole or fragmented monoclonals, polyclonals, and combinations as the assay format demands. The time it takes to develop and purify unique reagent antibodies demands that this start as early in the drug development process as possible.

Other critical reagents are those that impact the sensitivity, ruggedness, and consistency of the assay and especially include the detection system. It is a recommendation that a list of critical reagents and criteria for their acceptance be identified before initiating sample analysis. These must also be sourced, characterized, documented, and stored under conditions defined by stability investigation. When in-house reagents make up any part of the immunoassay, it is important to define and document the source, preparation, expiration, storage conditions, and acceptance criteria for their use to ensure a reliable result.

Once the final conditions are established, it is important to understand the assay's accuracy and precision capabilities because target criteria should be set for both before entering into validation. It is also good practice during validation to "stress the system" in a manner representing a true sample analysis run. Therefore, if the "batch" size is expected to be unusually large, a comparable batch, run during validation, should demonstrate that it could achieve the same acceptance criteria. It is particularly useful to evaluate the variability of QCs on every plate to predict the outcome expected during sample analysis.

The established/validated format should be used during sample analysis. Changes to the format must be revalidated to the extent that a consistent format is confirmed. The acceptability of changes to critical reagents should be documented before placing them into the sample analysis assays.

5.3.2.3 Specificity and Selectivity

One challenge of interpreting results derived from immunoassays is understanding exactly what the assay is detecting. Fundamental to this is knowing to what the antibody binds, that is, determining the antibody's specificity. A related parameter, selectivity, refers to the assay's ability to solely measure the target analyte in the presence of other protein constituents in the sample, some in very high concentrations.

Typically, experiments designed to determine the antibody's specificity involve assessing their cross-reactivity with similar compounds. When feasible, it is suggested that the sample matrix is spiked with physio-chemically similar compounds or variants of the target analyte.

Selectivity is the easier of the two parameters to assess experimentally. After the assay format is relatively fixed, multiple lots (at least 10 normals and 10 of the intended patient population in the case of clinical samples) of the sample matrix should be spiked near the lower limit of quantification and the recovery of the analyte should be calculated. The percent recovery of spike (expressed as relative error or %RE) is calculated as: 100× (observed mean conc − nominal concentration)/nominal concentration. This will aid in finally selecting a lower limit of quantification, before initiating assay validation.

An additional experiment to understand selectivity involves spiking both the diluent and the matrix with standard curve calibrators to detect matrix effects at all concentrations across the range of calibration.

Interfering substances, especially in patient populations, that require some evaluation may include prescription and over-the-counter medication, herbal medications, dietary substances, and even the presence of antidrug antibodies and associated immune complexes. During sample analysis, new matrix conditions may develop that would require further investigation and could include hemolysis, lipemia, rheumatoid factor, and so on.

Both specificity and selectivity experiments, if performed during the late development phase, after the assay format and critical reagents are fixed, may be cited in the validation report. Otherwise the experiments can be performed during validation. In both cases, the *a priori* acceptance criteria should be applied and acceptable recovery should be realized in at least 80% of the samples. Additionally, as lots of critical reagents are replenished, these types of assessments must reconfirm their acceptability.

5.3.2.4 Sample Collection Process/Matrix/Sample Preparation/Minimum Required Dilution

As mentioned, the ability of the antibody to bind to its target is the basis for assay sensitivity; therefore, maintaining the integrity of the analyte is vital. Frequently overlooked, the selection of sample matrix type and process for collection are crucial elements in bioanalysis. Rigorous investigation should go into the stability of the sample as it is collected, the anti-coagulant requirements, protease inhibitors, and other possible additives, and it should include the postprocessing storage. Furthermore, a process must be defined that provides for sample tracking "from cradle

to grave" documenting the chain of custody, the sample ID, and the time spent at each location and temperature through analysis. After analysis, the archival and destruction process should be identified.

For practical reasons, the matrix of choice for immunoassays is typically serum. The plate washers or automated systems used during sample analysis easily clog when plasma is used, which then has the potential to impact the validity of the result. However, protein analytes, including cytokines that are identified as labile and prone to degradation in serum, would preferentially be collected in plasma. When collecting citrated plasma, it is wise to clearly identify the salt form of citrate (Na, K, Li) so that it is transparent what the comparable matrix should be for QC preparation.

Whenever possible, the matrix expected in the samples should be used in the preparation of the standard calibrators and QCs. Individual donors (found acceptable when assayed as blank and spiked) are pooled to produce the standard curve and QC matrix; then aliquots are spiked to produce the standard curve and QCs. Some matrices are difficult to obtain. To accommodate this, as long as the QCs prepared in the intended matrix demonstrate the accuracy and precision expected, non-matrix standard curve calibrators are acceptable.

QC accuracy assessments can be challenging when the therapeutic drug shares an endogenous protein. In this case, the endogenous protein concentration can either be added to or subtracted from the final value. Before establishing the calculations, the necessary experiments must be performed, and the consistency of the endogenous value contribution must be documented.

In cases where the endogenous interferents do not generate a linear signal, then a minimum required dilution (MRD) may be applied. A MRD is the dilution of a matrix that finally permits an accurate and precise measurement of analyte. Although the diluting sample reduces the sensitivity of the assay, it may be required to develop and validate an accurate and precise method.

5.3.2.5 Standard Calibrators and Standard Curves

As described in the Guidance for the Industry, May 2001 [7], the "calibration curve is the relationship between instrument response and known concentrations of the analyte" in the matrix of interest. In immunoassays, the affinity and avidity of the antibody(ies) used to develop the standard curve are fundamental to the range because they define the sensitivity of the assay. The antibody (or pairs) once selected should be used throughout validation and sample analysis. During the development phase, it is a good idea to use many more calibrators and replicates evenly across the range to thoroughly describe the concentration-response relationship and to investigate the "best fit." Thereafter, select at least six to eight calibrators, over the entire range of the curve before the start of validation. Once validation begins, the standard curve calibrators should not be adjusted. Spiked standard curve points may be used outside the quantification range of the curve to help fit the curve, but they are not used in the assessment.

"Best-fit" can be evaluated in a straightforward manner by fitting several regression methods to the data generated during the development phase. The relative error of the back-calculated standard calibrators should be calculated. As expected,

the regression that consistently generates the most accurate and precise data is selected for confirmation in the validation phase. Usually a four- or five-parameter logistic with/without weighting describes the s-shaped immunoassay curve optimally; however, the smoothed spline has also been used with success with some platforms. It is important to critically assess whether the curves fall consistently above or below the expected concentration. This “trending” can invalidate a regression model.

5.3.2.6 Precision/Accuracy: Role of QCs

One function of the QC sample (or validation samples as they are sometimes called when used during the validation phase) is to mimic the study sample. Therefore, the therapeutic drug is spiked into a neat sample matrix, and not into a diluted or otherwise modified matrix. The QCs should be stored preferably along with the samples in the same freezer or at least in a comparable freezer. Documentation of freezer conditions will be critical to provide evidence that the conditions of samples and QCs are similar.

A second function of the QC sample is to measure the degree to which the assay is under control as determined by the assessment of accuracy and precision in multiple runs. Accuracy is described as the % relative error (%RE) or the amount the assayed value deviates from the nominal value. The precision is described as the % coefficient of variation (%CV) by dividing the standard deviation by the mean value recovered value.

During development, preliminary assessments are conducted to predict not only the QC concentration values to be used but also the target acceptance criteria. In this case, it is prudent to include more QC levels than will finally be used during validation. For instance, three levels prepared at the LLOQ will likely provide a clear indication of which QC is acceptable and where the assay cannot support the target acceptance. The same can be performed for the ULOQ. At least three levels between the two asymptotes are necessary because these will be used during sample analysis. For the validation process, five QC levels should be selected for testing, based on the accurate and precise readout: the final LLOQ to be confirmed; the LQC; less than three times the LLOQ; the MQC, placed about the middle of the curve; and the HQC, placed no more than 75% below the ULOQ and the ULOQ.

During validation, the five QCs should be tested in a minimum of six runs, at least in duplicate. It is not acceptable to discard any runs during this testing. The inter- and intrabatch precision and accuracy from all runs performed should be reported. It is generally expected that the precision and accuracy acceptance be at least 20–25% of the target range with a Total Error not exceeding 30%. (Total Error acceptance criterion is discussed later in this report.)

During sample analysis, only the LQC, MQC, and HQC defined during validation need to be run in duplicate with every assay. The precision and accuracy should conform to that established during validation. Typically, run acceptance criteria also require that at least one QC at each concentration level is acceptable, and that four out of the six QCs assayed must be acceptable. It is recommended that method acceptance criteria that are consistent with the validation be used during sample analysis [11, 12].

5.3.2.7 Range of Quantification

It is important to understand that the LLOQ and ULOQ have been selected because they define the true, accepted limits of the standard curve. Standard curve points below or above the LLOQ and ULOQ, respectively, are considered extrapolated and cannot be used to report sample concentrations. The LLOQ and the ULOQ validation samples and not the standard curve samples spiked into neat matrix define the standard curve range of quantification.

With certain toxicokinetic studies or therapeutic drugs dosed in high concentrations, the expected concentration in the sample may be well outside the quantification range as defined by the ULOQ. These samples must be diluted into the accepted range of the standard curve to determine an initial concentration and then multiplied by the dilution factor to determine the final concentration of the analyte in the sample. Although it is preferable to dilute the sample in matrix, in many cases, the process is performed in a buffer diluent.

5.3.2.8 Sample Stability (Bench Top, 4°C, –70°C)

The underlying reason that samples are tracked from "cradle to grave" is to document the integrity of the sample. Stability testing under all conditions to which a set of samples in a study is exposed supports the statement of integrity. Therefore, such testing of QC samples in matrix comprises evaluating stability during sample collection and processing: –20°C or –70°C long-term storage to cover the time from when the sample is processed to its final analysis, bench top under conditions similar to analysis, resident time in laboratory refrigerators and freezers, and freeze-thaw to cover the expected or possible cycles. Another consideration is to test the stability of the analyte in intermediate stock solutions if stored for later analysis.

The samples should be thawed under the same conditions used to thaw study samples. Similarly, refreeze the samples for a length of time that would ensure complete freezing, usually 12–24 hours. Samples should be assayed using a freshly prepared standard curve, and acceptable QCs should be used to monitor assay performance. The stability samples should meet the criteria for acceptance as defined for in the validation plan.

5.3.2.9 Dilutional Linearity and Parallelism

Dilutional linearity is the ability of a QC sample spiked at a high concentration (at least as high as the expected C_{max} in a study) to be acceptably diluted into the range of the standard curve so that the initial concentration determined off the regression and multiplied by the dilution factor produces a final concentration with an accuracy and precision expected for that assay. Usually, serial dilutions are employed to ensure that at least two to three fall on the acceptable range of the curve so that linearity can be demonstrated. When a study design produces samples that require a dilution greater than that established, it is advisable to employ an equivalent dilutional QC that is run in the assay.

To evaluate the "hook effect," dilute a very high QC (100- to 1000-fold greater than the ULOQ) so that the expected concentration read off the regression reads above the ULOQ.

Parallelism is determined in a manner similar to dilutional linearity but with incurred samples. This is usually not possible until after the initiation of a study. When incurred samples are available, one strategy is to pool the C_{max} samples to create parallelism QCs. Serially dilute the sample so that at least two to three fall on the acceptable range of the curve to demonstrate linearity.

5.3.2.10 Robustness and Ruggedness

Robustness and ruggedness experiments are used to demonstrate how reproducible a method is when conditions vary. An assay method protocol defines the exact steps to be followed to ensure an accurate and precise result. Unfortunately, slight-to-large deviations occur in the everyday process, which may or may not impact the result. Assay conditions like incubation temperature or exposure to light define the robustness of the assay, whereas changes to the routine, for instance, multiple analysts or different instruments, define the ruggedness. The actual batch size for a routine sample analysis run is frequently overlooked but is often an impactful ruggedness measurement that should be assessed.

5.3.2.11 Run Acceptance Criteria

Because validation QCs are used to assess the overall accuracy and precision of the method during the validation phase, no runs initiated for validation may be eliminated due to QC failure. Therefore, the acceptance criteria for the standard curves are used to accept each assay. At the conclusion of the validation, run acceptance criteria for QCs to be used in-study are summarized and run acceptance criteria are established based on this data.

During sample analysis, the standard curve should be evaluated for acceptance before evaluating the QCs. Once the curve has been accepted, then the performance of the QCs should be evaluated. The acceptance criteria established during the precision and accuracy (4–6–20 rule) should be followed as described.

5.3.3 PARTIAL VALIDATION, METHOD TRANSFER, AND CROSS-VALIDATION

Method validations can be classified into three broad categories, full, partial, and cross. A full validation is done for any new methods and involves method development, prestudy, and in-study validation. It is essential that a full validation be conducted for changes in species (e.g., rat to mouse), change in matrix within a species (e.g., rat serum to rat urine). However, a partial validation is sufficient when a minor change is made to an already fully validated method as described below.

5.3.3.1 Partial Validation

A partial validation is conducted when minor changes to a method are made. These may include method transfer, changes to anticoagulant (e.g., EDTA, heparin, citrate), changes in the reagents used in the method (especially pivotal reagents

such as the primary antibody or secondary antibody), sample processing changes (e.g., how fast a clot needs to be spun, collection vessels, and storage condition), changes to sample volume (e.g., if the volume of sample is changed from 100 to 200 μL per well), extension of the concentration range, selectivity issues (e.g., different disease population and concomitant medication), conversion of a manual to an automated method, qualification of an analyst, and so on. Partial validations can range from a single intra-assay accuracy and precision run to a nearly full validation. Although sample-processing changes may only require one run, several runs would typically be expected for changes to lots of reagents. Transferring an analytical method may require substantially more experimentation. Typically, for partial validations, three accuracy and precision runs are conducted and the inter-assay accuracy and precision criteria are compared against the original validated assay. If these criteria are met, the change to the method will be accepted and the proper documentation should be made to the method or method standard operating procedure (SOP). Other validation parameters have to be compared depending on the situation where these experiments are conducted to scientifically justify the change; e.g., if the method is to be used with a diseased population different to the original intended use of this method, then additional selectivity experiments must be conducted to evaluate the matrix effect.

5.3.3.2 Method Transfer

Method transfer is the situation in which the method is fully validated in one laboratory (sending laboratory) and transferred to another laboratory (receiving laboratory) and requires at least a partial validation. The parameters to evaluate during this partial validation are accuracy and precision of the method, selectivity, bench-top stability, and so on.

In addition to the required documentation (e.g., method description, validation report, and certificate of analysis), the sending laboratory should provide information on those factors that may affect the ruggedness of the assay (e.g., identifying pivotal reagents and material). The method transfer process can be conducted in a multiphase manner, a transfer phase in which the sending laboratory participates in the transfer of the method at the receiving laboratory; the feasibility evaluation phase, in which the receiving laboratory runs the assay independently; the validation phase, which could be the phase where the partial validation is conducted; and finally a qualification phase in which both the sending and the receiving laboratory assays blinded samples. The method transfers require a plan or protocol that defines the process (e.g., experiments to be conducted) and the acceptance criteria. It is not uncommon for the sending laboratory to send personnel to physically demonstrate and train the personnel at the receiving laboratory.

Once the transferred method is validated at the receiving laboratory, an ideal scenario is to have both the sending and the receiving laboratories analyze blinded, 30 spiked samples covering the standard curve range, and 30 pooled incurred samples. The two sets of data may be compared by using a predefined statistical equivalence test [12, 13]. Alternatively, the differences between the two sets of data may be compared using an agreed to range of acceptability. Any acceptance criteria must be set *a priori* and documented in a plan or protocol before executing this phase of the method transfer process.

5.3.3.3 Cross-Validation

Cross-validation is conducted when two validated bioanalytical methods are used within the same study or submission, for example, ELISA assay to Biacore and ELISA to a liquid chromatography/mass spectrometry. It is recommended that test samples (spiked and/or pooled incurred samples) be used to cross-validate the bioanalytical methods. Data should be evaluated using an appropriate predefined acceptance criteria or statistical method [12, 13]. It should be cautioned that many times the methods that are being cross-validated may not have the same range of quantification. In these situations, it is necessary to prepare spiked samples within the range that are common to both methods for comparison.

5.3.4 TOTAL ERROR VERSUS 4–6–20 RULE

5.3.4.1 Total Error

The total error of a measurement takes into account both the systematic error (bias) and the random error components. Any measurement that is made during an experiment consists of both of these error parameters, and it is not possible to separate these two. Therefore, it is scientifically correct to use the total error criteria to assess the acceptability of a quality control result during a run.

As described in this chapter, prestudy validation runs are accepted based on the standard-curve acceptance criteria. No run acceptance criteria are applicable for prestudy validation sample assessments; i.e., no run can be rejected due to poor validation sample performance during accuracy and precision evaluation, and all data from the prestudy validation runs are reported without exceptions. In some cases, there may be assignable cause (e.g., technical issues) for removal of a validation sample data point before the calculation of the cumulative mean. Exclusion is applied at the end of the validation study period and must be documented as described in the documentation section.

For each in-study run, the standard curve must satisfy criteria described in the standard-curve section; however, run acceptance is based primarily on the performance of the QC samples. When using total error for ligand binding assays of macromolecules, the run acceptance criteria recommended in the precision and accuracy section requires that at least four of six (67%) QC results must be within 30% of their nominal values, with at least 50% of the values for each QC level satisfying the 30% limit. The recommended 4–6–30 rule imposes limits simultaneously on the allowable random error (imprecision) and systematic error (mean bias). If the application of an assay requires a QC target acceptance limit different than the 30% deviation from the nominal value, then prestudy acceptance criteria for precision and accuracy should be adjusted so that the limit for the sum of the interbatch imprecision and absolute mean RE is equal to the revised QC acceptance limit.

5.3.5 DOCUMENTATION

It is critical to document the information generated during the development of a method in a laboratory notebook or other acceptable format. Information on the

following assessments should be generated during assay development: critical assay reagent selection and stability, assay format selection (antibody[ies], diluents, plates, detection system, etc.), standard-curve model selection, matrix selection, specificity of the reagents, sample preparation, preliminary stability, and a preliminary assessment of assay robustness. At the end of the development portion of the assay life cycle, a draft method or an assay worksheet should be generated to be referred to during the prestudy validation.

A validation plan should be written before the initiation of the prestudy validation experiments. Alternatively, reference to an appropriate SOP can be made to ensure that a documented outline exists for the experiments required for prestudy validation. This plan can be a stand-alone document or can be contained in a laboratory notebook or some comparable format. The documentation should include a description of the intended use of the method under consideration and a summary of the performance parameters to be validated that should include, but may not be limited to, standard curve, precision and accuracy, range of quantification, specificity and selectivity, stability, dilutional linearity, robustness, batch size, and run acceptance criteria. The plan should include a summary of the proposed experiments and the target acceptance criteria for each performance parameter studied.

After completion of the validation experiments, a comprehensive report should be written. The format of the report may be dictated by internal policies of the laboratory; however, such reports should summarize the assay performance data and deviations from the method SOP or validation plan and any other relevant information related to the conditions under which the assay can be used without infringing the acceptance criteria.

Cumulative standard curve and QC data tables containing appropriate statistical parameters should be generated and included with the study sample values in the final study report. Unlike the prestudy validation, failed runs are not included in these tables. Additional information to be included in the final report is a description of deviations that occurred during the study, a table of the samples that underwent repeat analysis and the reasons, and a table with details on all failed runs.

5.3.6 CONCLUSION

The primary focus in the analytical considerations of immunoassays for macromolecules should be in the development phase. By thoroughly defining each component of the immunoassay in the first phase of the assay life cycle, the resulting validation plan should be concise and the validation process should be straightforward. Several facets of the assay defined in the late development stage, such as specificity and dilutional linearity, can appropriately be included in the final validation report.

A typical validation will include at least six precision and accuracy assays to define the consistency of the assay. Within those assays, several parameters can be defined, including early stability, specificity, selectivity, and range of quantification. No assay run should be eliminated except for a true and documented analyst's error.

The validation QC samples define the range of the assay, and no values below the LLOQ or above the ULOQ may be reported. Within the six validation assay

runs, the validation samples are used to define the cumulative precision and accuracy. During validation, no validation sample may be eliminated to show the true profile of the assay.

During sample analysis before assessing the QC samples for acceptance, the standard curve must be deemed appropriate by predetermined criteria. Only after the curve is accepted may the assessment of QC samples continue. QC sample results determine whether the assay run is valid. Acceptance criteria can be based on 4–6–20 rule or on Total Error and should be predicated on the criteria used in both the development and the prestudy validation phase. Overall, the immunoassay is a highly sensitive assay that can be used to quantify protein and peptide drugs in a biological matrix, often routinely in the pg/mL range.

5.4.1 INTRODUCTION

Since the first commercial introduction of high-performance liquid chromatography (HPLC) in the 1970s, this versatile method has gained wide popularity, resulting in a phenomenal increase of successful applications described in literature. HPLC is a highly efficacious method in peptide and protein analysis especially for the preparation of samples for further analysis by electrospray mass spectrometry or quantification using amino acid analysis. This story of success is related with the continuous development and miniaturization of flow rates and column diameters and the high level of automation combined with the reliability of the instruments. Today HPLC can separate minute amounts of peptides and proteins and find those areas of biochemistry and biotechnology where only small amounts of sample are accessible. The following chapter is focused on the analytical aspects of liquid chromatography of biomolecules from amino acids to proteins.

5.4.2 BASICS OF CHROMATOGRAPHY

5.4.2.1 Hardware Requirements

The chromatography-based separation of amino acids, peptides, or proteins has to be divided into the different applications of preparative and analytical chromatography. For analytical HPLC, the identification and quantification of single components from a low complex mixture is the most important task. Therefore, the analytes of interest have to be separated as much as possible.

The preparative biochromatography is focused on the isolation and enrichment of a single protein species. Typically, the HPLC separation is performed with bigger columns providing higher loading capacities but relative short column lengths in order to keep separation time short. However, in this chapter, we will focus on the analytical aspects of HPLC separation.

Generally, solvent pumps with high pressure capability are required for HPLC due to the backpressure generated by the dense package of the column resin. The typical specifications are pressure limits of about 400 bar and 5800 psi, respectively, although this limit is normally not required. Recently, new column materials with small particle sizes of about 1.3 μm have been introduced that require HPLC pumps and tubings that resist pressures of up to 1000 bar (approximately 14,000 psi) [1–3]. For the separation of biomolecules, two different HPLC-pump types have been established: piston pumps and syringe pumps.

The basic principle of a syringe pump principle is simple: A motor activates a piston that pressurizes the solvent within a syringe. Although this type of a pump was widely used in the past, the syringe pump has some limitations; e.g., it usually cannot deliver the same high-pressure limits as stainless steel piston pumps. In addition, the amount of solvent for a single chromatographic separation is restricted to the syringe volume. Moreover, these pump systems are most often designed for binary gradients because for each solvent, an syringe pump is required. Recently, syringes have experienced a revival due to their scalability to smaller dimensions, which enables access to native nanoscale flow rates [4, 5]. Nevertheless, piston pumps are the pump systems that are provided by all major vendor companies

because of several imminent advantages in flexibility and performance. A small piston pressurizes the solvent continually within the flow system. Check-valves prevent the backflush of the solvent. The refilling of the piston causes pulsation, which can be eliminated by using a second pump unit that performs the pump stroke while the first piston refills. The gradient is formed by a mixing device that can be located at the high- or low-pressure side, i.e., before or after the pump unit. Syringe pumps normally use a mixing-tee located directly after the two syringes. The gradient is formed by different movement speeds of the syringes.

Piston pumps can be designed for low-pressure mixing as well as for high-pressure gradient formation. The low-pressure mixing is realized by solenoids that open the flow path of a solvent for a discrete period of time. Subsequently, the solvents are mixed and pressurized. This setup applies only to a single pump unit, whereas high-pressure mixing in piston-pump systems requires a single pump unit for each solvent. The major advantage of this setup is the enhanced response time to changes in the gradient, which is required for steep and short gradients. Another aspect of HPLC pumps for biochromatography is the availability of bio-inert versions, which can be of importance for several applications covering extreme pH-values as well as several modified peptides that are retarded by stainless steel [6]. In contrast to stainless steel, all components of the flow-path are composed of inert materials like PEEK, Titanium, or Saphire (for the pistons).

Besides the pump as a solvent delivery device, the HPLC valves are important components for switching solvent lines (e.g., injection loops and parallel column setups). They are designed to resist the applied pressure and feature a small dead volume to prevent peak dispersion. HPLC valves are available in different switching modes and port numbers. Additionally, valves are also fashioned as bio-inert versions. For several applications, the HPLC column should be used in a column-oven for ensuring constant temperature during separation.

To introduce samples into the flow path, the easiest way is the usage of a sample loop that is connected to an HPLC valve. After loading and switching, the loop is integrated into the flow path and the sample is delivered to the separation column. Today, this task is done by autosamplers that can temper samples and provide 24 hours of fully automated and reproducible sample injection.

A further important component of each HPLC system is the detection device. Often, Ultraviolet (UV)-detectors are used for this purpose because many analytes absorb light in the range of 200–350 nm. UV detectors provide reasonable sensitivity and dynamic range as well as a low noise level.

Recently, multi-wavelength detectors that can switch between different wavelengths have been used. Diode array detectors (DADs) use a light source that is dispersed by a holographic grating after transmission through the flow cell. The light of the single wavelengths is reflected onto a diode array with several hundreds of diodes acquiring in real time a full-spectrum chromatogram. This leads to a better characterization of each eluted component.

Electrochemical detectors are applied for analytes that are capable of redox-reactions. The application field of biochromatography for PADs covers only a small spectrum of amino acids, whereas a broad range of applications is established for smaller molecules.

One of the most important detectors for proteins and peptides is a mass spectrometer that is necessary for structural analysis of peptides. The high sensitivity

and capability of structural information are the two major reasons for the success of HPLC coupled to mass spectrometry in proteomics.

Often, a pressure is applied to generate the mobile phase flow though the column. Alternatively, in capillary electrochromatography (CEC), an electric field is applied along the column to drive the mobile phase through packed capillary columns with internal diameters (IDs) of 50–100 μm. This principle was proposed by Pretorius et al. [7] and further developed by other groups [8, 9]. In these electrically driven systems, the mobile phase flow is characterized by a flat velocity profile, which results in higher separation efficiencies. However, ineffective heat dissipation restricts the use of high electric field strengths for large ID columns and thereby limits the applicability of the technique.

5.4.2.2 HPLC Columns

The efficiency of an HPLC column is determined by the type of stationary phase particle and the quality of the column packing. The internal diameter of the column is not affecting the performance characteristics [10], although it has been deliberated that columns with low aspect ratio, i.e., ratio between internal diameter and particle diameter, have higher separation efficiency. A recent and extensive experimental study did not show convincing evidence for higher column efficiency for columns with an aspect ratio from 7.5 to 30 [11].

A more effective way to increase the efficiency in HPLC is by reducing the stationary phase particle size, as predicted by the well-known van Deemter equation [12], which describes the plate height in HPLC as the sum of different contributions. In this respect, submicron particles have been applied and efficiencies up to 730,000 plates/m have been reported for small molecules [13, 14].

However, as a result of the increased flow resistance of these submicron particle packed columns, extremely high pressures of 200–300 MPa are necessary to drive the mobile phase. Working at these high pressures, several phenomena should be taken into account: (1) increased viscosity of the mobile phase affecting the efficiency and pressure drop over the column, (2) Joule heating effects that may cause radial temperature gradients in analytical and narrow-bore columns, and (3) linear velocity surge caused by mobile-phase compression responsible for band broadening [15].

Recently ultra-performance liquid chromatography (UPLC) has been introduced commercially as a new direction in liquid chromatography. In UPLC columns packed with 1.7-μm, particles are operated at pressures up to 100 MPa. The main advantage is obviously the reduction in analysis time that has been demonstrated for pharmaceutical analysis [16] and metabolomics [17].

The use of monolithic columns in LC has advanced rapidly since their first introduction in the 1990s [18–21]. In contrast to capillary columns packed with particulate stationary phases, monolithic columns consist of a single continuous support. Monolithic stationary phases can be subdivided in two classes, i.e., polymer- and silica-based materials.

Polymer monoliths are prepared by *in situ* polymerization of monomers such as styrene, acrylate, methacrylate, acrylamide, or cyclic compounds and have been reviewed thoroughly [19]. The selectivity of the monolithic column can be changed by incorporation of functional monomers during the polymerization. A

disadvantage of this procedure is that for each polymerization mixture, the conditions have to be optimized. Alternatively the functionality can be modified at the surface of the monolithic structure by (photo)grafting [22].

Silica monoliths are prepared by sol–gel technology starting from alkoxide precursors, such as tetraethoxy-silane or tetramethoxy-silane [23]. The structure of a silica monolith is characterized by an interconnected silica skeleton and bimodal distribution of 1–3-μm macropores (flow through pores) and 10–20 nm mesopores.

The main advantages of monolithic columns are the superior separation performance and low flow resistance. In addition due to their continuous nature, frits are not required to retain the stationary phase. The production process of monolithic columns is more flexible than that of packed columns; e.g., photo-polymerization can be applied to prepare monolithic structures or add selectivity locally. Both polymer- and silica-based monolithic capillary columns have been used for highly efficient separations in LC–mass spectrometry (MS) applications for proteomic research [24, 25].

5.4.2.3 Miniaturization of HPLC

Miniaturization in HPLC was started more than 25 years ago and was mainly driven by the need for analyzing minute samples [26–29]. The developments were accelerated by the widespread utilization of electrospray ionization (ESI) for interfacing LC and MS.

Reducing the ID of the LC column offers several advantages, among which are most importantly: (1) increased mass sensitivity for concentration sensitive detectors due to reduced chromatographic dilution, (2) easier coupling to MS interfaces [ESI and matrix-assisted laser desorption/ionization (MALDI)] due to the lower flow rates, and (3) a lower stationary phase and solvent consumption.

The increased mass sensitivity for concentration-sensitive detectors is the direct result of reduced dilution of the sample in small ID columns and is inversely proportional with the square of the reduction in column diameter. As a result of miniaturization in LC, a variety of new column formats were developed, which can be subdivided according to the ID. In Table 5.4-1, the ID, typical flow rate, and sample loading are listed for various HPLC techniques.

Analytical and narrow-bore HPLC columns are most commonly used for routine analysis, which require the highest possible robustness. Capillary- and nano-LC columns find application in various fields of biotechnology research, mainly for sample limited analysis of peptides and proteins [30–32].

TABLE 5.4-1. Typical Dimensions and Flow Rates for Analytical RP Chromatography

	Inner Diameter	Flow Rate	Relative Gain in Sensitivity
Conventional LC	4.6 mm	1000 μl/min	Baseline = 1
Narrowbore LC	2.1 mm	200 μL/min	5
Microbore LC	0.5–1.0 mm	50 μL/min	35
Capillary LC	180–300 μm	2–5 μL/min	200
Nano LC	50–100 μm	200 nL/min	3500

A significant reduction of the column ID put stringent demands on the instrumentation for micro-LC as all volumetric extra-column dispersion contributions must be down scaled accordingly. Initial developments in this area were achieved on modified standard LC instruments. For approximately 10 years, dedicated instrumentation for micro-, capillary-, and nano-LC has become commercially available and was recently discussed [33].

The reduction or downscaling factor in going from an analytical to a capillary column equals the ratio of the square of the column diameters. Downscaling from a 4.6-mm ID standard HPLC column to a 300-μm ID packed capillary column equals a theoretical factor of 200 in sensitivity (see Table 5.4-1). This factor applies to all components of the LC system, like flow rate, injection and detection volume, and connecting capillaries [34]. Likewise, for a 300-μm ID capillary column, the flow cell volume must be reduced to ~50 nL to prevent extra-column peak broadening. For injection of the sample, the downscaling factor implies that an injection volume of 20 μL on a 4.6-mm ID column equals an injection volume of ~90 nL on a 300-μm ID capillary column. Consequently autosamplers used for capillary LC must be able to inject nanoliter volumes in a reproducible manner. However, in gradient elution, the preferred mode of operation for separation of peptides and proteins, sample preconcentration can be applied. Relatively large volumes, often exceeding the column volume several times, are injected while the compounds are concentrated at the head of the column or trap column. In nano-LC with typical flow rates of 100–300 nL/min, column switching is a widespread technique, e.g., for peptide mapping when the sample amount is limited. A trap column is mounted onto a switching valve (see Figure 5.4-1) to reduce the sample volume from several microliters present in the sample loop to a few nanoliters (basically the volume of the trap column). After sample loading, the trap column is switched in line with the separation column before starting the HPLC gradient. An additional advantage of column switching is the ability of online sample desalting. A common setup for

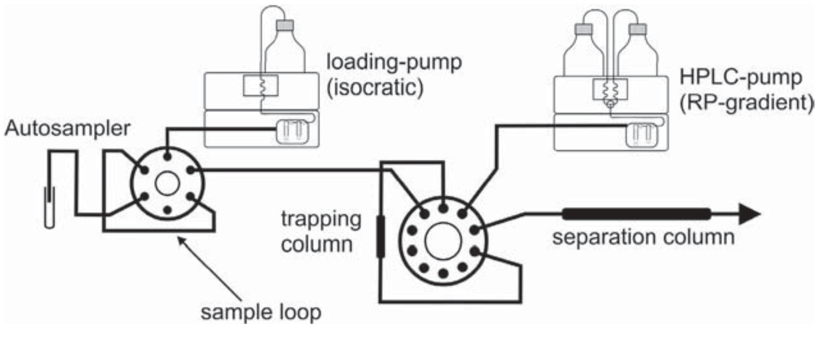

Figure 5.4-1. Schematic overview of typical reversed phase-HPLC with precolumn and column loading for peptide separation. The central switching valve has two positions: In position one, the sample is loaded onto the precolumn with the loading pump. After trapping and desalting of the sample, the valve is switched and the precolumn is integrated into the flow of the gradient pump. By increasing the amount of solvent B, the single peptides are separated on the separation column and afterward detected with a UV-detector and/or by mass spectrometry.

column switching in nano-LC is shown in Figure 5.4-1, although other configurations have been described as well [35, 36].

Typical flow rates applied in nano- and capillary-LC are in the range of 50 nL–10 µL/min according to Table 5.4-1. HPLC systems that can generate mobile phase gradients at these flow rates are available and are based on either flow splitting or dedicated micro- or nano-pumps. The generation of gradient profiles should be characterized by small delay volumes, efficient mixing, high accuracy, and acceptable reproducibility. Significant improvements in this respect have been achieved during the last couple of years, partly due to the incorporation of liquid flow sensors that can measure flow rates down to several nanoliters/minute. With current state-of-the art instrumentation, it is now possible to generate solvent gradients with a reproducibility better than 0.3% RSD at flow rates suitable for nano-LC.

5.4.3 SEPARATION OF PEPTIDES

5.4.3.1 Short Introduction

Reversed phase (RP) chromatography has been established as the superior separation technique for peptides. The chromatographic resolution of this method is higher compared with other methods like ion-exchange (IEX) or size exclusion chromatography (SEC).

5.4.3.2 Reversed Phase Separation of Peptides

RP–HPLC is well suited for direct online coupling with electrospray ionization–mass spectrometry (ESI–MS) due to solvent compatibility with the electrospray ionization technique.

The common gradient for peptide separation consists of a binary solvent system containing in solvent A: 0.1% formic acid and in solvent B: 0.1% formic acid and 84% acetonitrile. If no high-sensitive MS detection is required, formic acid can be replaced by TFA. For solvent B, the amount of TFA has to be reduced to 0.08% to prevent baseline shift during the gradient run time.

Gradients normally begin at 5% B with a linear increase to 50% B within 45 minutes. For rinsing the column, the percentage of B is increased to 95% and held for 5 minutes. Afterward the column is re-equilibrated to 5% B. Therefore, the complete gradient is finished within 1 hour. Extension to longer and thus shallower gradients is suggested if complex samples have to be separated.

The formic acid acts as an ion pair reagent that masks the peptide-charge and increases the hydrophobicity for better retention on reversed phase supports. Trifluoroacetic acid (TFA) has better characteristics for HPLC separation because of less UV absorption at 215 nm and superior properties as an ion pair reagent [37, 38]. Therefore, it is preferably used in solvents for loading on precolumns or separation without the need for MS detection. In this context, the usage of formic acid as an ion pair reagent instead of trifluoroacetic acid, which has less absorption in the UV range, is preferable because of its better ionization efficiency in MS ion sources. In contrast, TFA offers less UV absorption and superior separation results at the cost of inferior ionization rates.

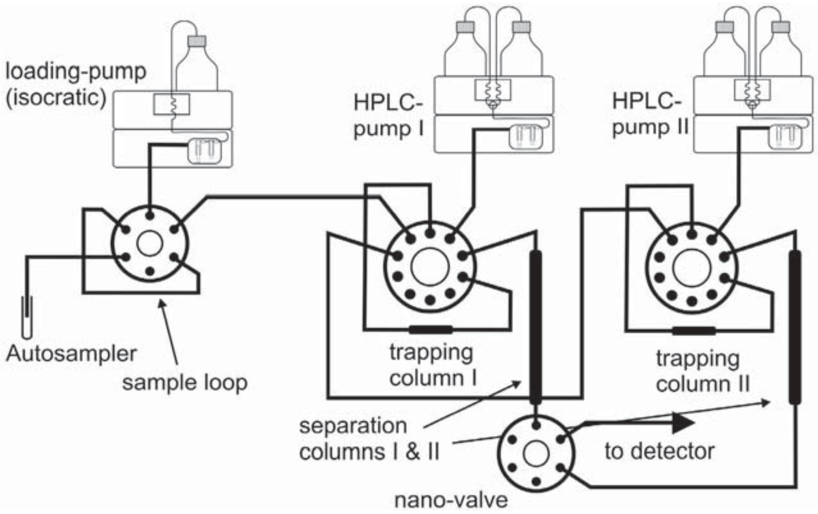

Figure 5.4-2. Set up of a dual-gradient HPLC system. This HPLC-system consist of a normal reversed phase separation system with an additional gradient pump and HPLC-valve. Two complete sets of pre- and separation columns are required. This setup enables the equilibration and sample preconcentration on the one column pair, whereas on the second column pair, the separation is performed. This reduces the dwell time of a connected mass spectrometer and thereby increases the sample throughput per day significantly. The final nano-valve directs the flow of the active separation column to the connected detector.

MS represents the most expensive part of a nano-LC–MS systems. Therefore, dwell times are expensive and should be reduced to a minimum. Parallel LC-systems consist of a more complex setup with two pairs of pre- and separation columns (see Figure 5.4-2).

CARLA Test. Dead volume is a serious obstacle for high-resolution RP separation using nano-HPLC. A dead volume acts as a passive mixing chamber in the flow path that levels the preformed gradient, thereby leading to peak broadening and reduced sensitivity. The definition of a dead volume is a relative subject because a 0.5-μL dead volume in a preparative HPLC with a 1-mL/min flow rate and a step-gradient is not recognized as such. But the chromatographic separation would fail in the case of a nano-HPLC with typical flow rates of 200 nL/min. For this reason, the detection of dead volumes that cannot be visually located is a very important task for the highest performance and sensitivity. The CARLA Test provides a very simple approach for online detection of dead volumes in HPLC systems [39]. For the test, a UV detector, a precolumn system with a loading pump using 0.1% TFA and the nano-HPLC-system using 0.1% FA, is required.

While the sample is loaded onto the trapping column and desalted by flushing with 0.1% TFA at an increased flow rate, the nano-HPLC branch is equilibrated with 0.1% FA. The UV baseline is set on the FA containing solution. By switching the HPLC valve, the trapping-column loop is then integrated into the nano-flow. Now, the nano-flow pushes the small volume of TFA solution through the

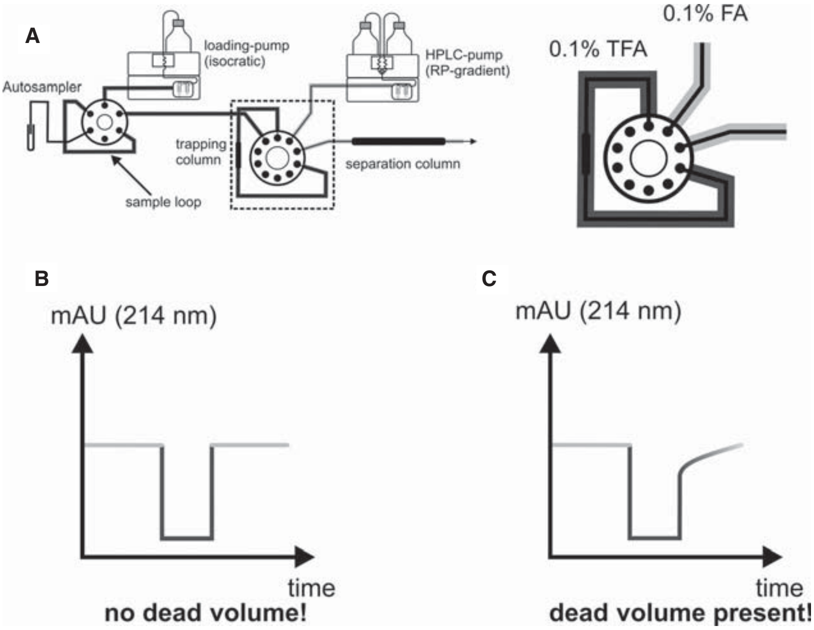

Figure 5.4-3. Carla test. (A) The Carla test requires the detection of the UV-trace at 214 nm and a precolumn setup with loading pump that delivers 0.1% TFA for peptide trapping and desalting and a nano-flow system working with 0.1% FA for peptide separation. The close-up view of the HPLC valve depicts the localization of TFA and formic acid. (B) Schematic UV-chromatogram after the switching event. The baseline is set to UV-absorption level of formic acid. The elution of TFA from the precolumn loop decreases the UV-signal to a significant level. If no dead volume is present, the signal has a rectangular shape. (C) If a dead volume acts as a small mixing chamber, the discrete volumes of TFA and FA are partially mixed, leading to long transitions back to baseline. In this case, eluted peptide peaks are broader and sensitivity level of such a HPLC-system is decreased.

trapping-column loop and the separation column to the UV detector that is reported by a signal drop. If no mixing occurs, the pattern should be shown as a sharp rectangular signal (see Figure 5.4-3B). However, if a dead volume is present, the two different solutions are mixed during passage through the flow path (see Figure 5.4-3C). This results in a smooth transition back to the FA baseline after an increased amount of time.

5.4.3.3 Column Media and Resins

The performance of HPLC separations depends on the quality of the applied column. Column dimensions as well as the used resins are the main features that have to be regarded. Although column systems with beads as chromatographic material have been extensively used, recently available monolithic columns represent a completely new technology.

Bead materials are normally made of silica spheres or synthetics like polystyrenedivinylbenzene (PS-DVB). The beads are then functionalized with the appropriate chemical group for interaction with analytes. In the case of peptides, C18- or

C8-phases are coupled to the silanol groups on the bead-surface with chlorotrialkylsilane reagents. Often, not all available silanol groups are modified and are often blocked by end-capping to avoid ion exchange functionality interfering with the RP mode. PS-DVB materials are hydrophobic in nature and need only surface modification if other separation properties are required. The silica-bead packed columns provide a very good resolution for HPLC, but they are becoming unstable above pH 8. Under basic conditions, polymeric materials are therefore preferable. However, several vendors have developed chemical modifications on silica beads that slightly increase the stability of the material up to pH 9–10.

The pore diameter of the beads has a decisive influence on the binding capacity of the column, which means that small pore sizes increase the effective surface of the material and thereby the binding capacity. Nevertheless, if the pores are too small, the peptides cannot diffuse and therefore the interaction of the analyte and the stationary phase is suppressed. A pore diameter of 100 Å has proven to be very suitable for tryptic peptides, whereas high-molecular-weight peptides should be separated using 300-Å pore material. The bead size and the bead size distribution have a direct influence on the separation efficiency, which is expressed in the van Deemter-equation by the Height Equivalent to the Theoretical Plate (HETP). The smaller the bead size, the smaller the plate height and the higher the resolution. But with smaller bead sizes, the required flow rate has to be increased and therefore the backpressure rises significantly. Typically, analytical RP columns for peptides use bead sizes between 3 and 5 μm. The column diameter and the column length depend mainly on the required resolution and the available sample amount, respectively.

5.4.3.4 Multidimensional Separation of Peptides

Proteins differ in molecular weight, hydrophobicity, charge, and structure over a wide range, which renders it impossible to apply a single chromatographic separation for complex protein mixtures. Therefore, proteins are digested to peptides to reduce the huge differences in their physico-chemical properties that enables the application of the peptide mixture to chromatographic separation approaches. However, the digest increases the number of analyte species from the protein to the peptide level significantly. For instance, the expected number of proteins in a cell differs from 5 to 20,000 species. After digestion the expected number of peptides ranges between 50,000 and 200,000 species. Such complex samples can only be handled by multiple separation according different separation parameters. Generally, the concept of this approach is the subsequent separation and prefractionation of peptides with different chromatographic media. In most cases, the first dimension represents a strong IEX Chromatography where the peptides are fractionated during fixed time intervals. Afterward, each ion-exchange fraction is applied to an RP column as the final high-resolution separation dimension that is usually online-coupled to an MS representing an additional gas phase separation dimension with concurrent peptide analysis. Several different applications have been developed so far: offline or online MDLC, MudPIT, and the COFRADIC [40] technology.

The classic MDLC technique separates the peptides using a strong cation exchange (SCX) column for the first and C-18 RP material for the second

dimension. Offline and online separation, respectively, differs in peptide transfer from the first to the second HPLC-separation dimension. For the online mode, eluted fractions are directly transferred to the next dimension, whereas during offline MDLC, the collected fractions are prepared for injection onto the RP column. The usage of fraction collectors and liquid handlers enables a semi-automated sample preparation before reinjection for RP separation and subsequent analysis. The advantages of the offline mode are the application of continuous gradients and more flexibility in solvent selection, thereby leading to a more effective elution and better resolved separation (see Figure 5.4-4). Additionally, both separation dimensions can be performed subsequently on a single HPLC system with less hardware requirements in contrast to the online system.

Online MDLC works in full automation mode and integrates first- and second-dimension separation into a single system, providing high sample throughput capabilities and short dwell times. The elution of the SCX column is performed with salt-plugs (see Figure 5.4-5) or step-gradients (see Figure 5.4-6) with increasing salt amounts. Subsequently, the eluted fraction is trapped onto an RP-precolumn where the peptides are desalted and concentrated. Then the HPLC valve is switched, and the precolumn is introduced into the flow path of the RP gradient. Peptides are separated and eluted similar to common RP separations. After the complete RP run, the precolumn is switched back and traps the next fraction eluting from the IEX column. In more complex MDLC systems, two or more precolumns are alternately used for trapping and elution to reduce the complete run time as well as to enable the application of continuous IEX gradients. A general disadvantage of the online system is the restriction to non-organic solvents for IEX elution. It has been shown that little amounts of organic modifiers increase the elution efficiency and prevent memory effects during the first dimension [41]. In online systems, this

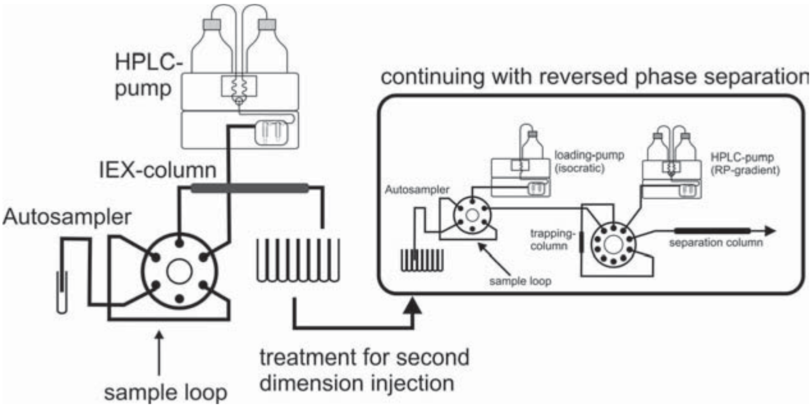

Figure 5.4-4. Scheme of an offline MDLC setup. The separation with this two-dimensional HPLC separation is divided into two steps. At the first step, the analyte is separated by an ion-exchange separation (IEX) and the eluted fractions are collected. Before the second step, the samples are concentrated and desalted and organic modifiers are removed if present. The second dimension is performed by a normal reversed phase-HPLC separation (see Figure 5.4-1). If the required capacities are not available, this type of MDLC run enables the separation of both dimensions on the same HPLC after a setup change of column and solvents.

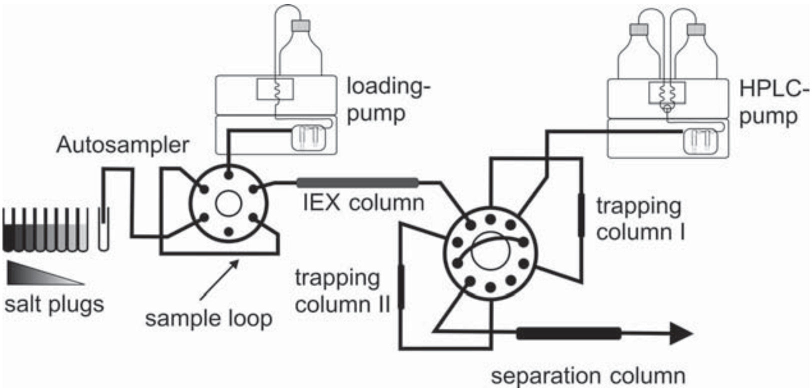

Figure 5.4-5. Online MDLC using salt-plugs. This HPLC separation mode uses salt-plugs with increasing salt concentrations that are injected by the autosampler onto the IEX-column to elute stepwise stronger bound peptides.

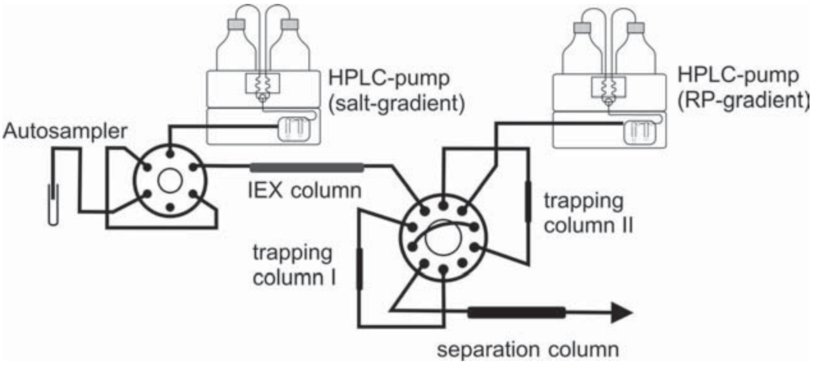

Figure 5.4-6. Online MDLC with gradient elution. This type of MDLC system is similar to the setup with salt-plug elution, but in this case, the elution is performed with a step- or linear-gradient that requires a second gradient capable HPLC-pump.

would result in inferior peptide recovery because the SCX-peptide fraction would not be trapped quantitatively on the precolumn due to the organic solvent.

This type of elution has the further disadvantage that peptides are present in different fractions due to memory effects. Additionally, the online systems consist of multiple HPLC pumps and valves, several connections, and a complex control program that gives rise to many potential sources of error as well as to difficulties in obtaining acceptable sensitivity. The multidimensional protein identification technology (MuDPIT) was designed to provide a high-resolution peptide separation technique for electrospray ionization mass spectrometry (ESI–MS) with a very good sensitivity [42] (see Figure 5.4-7). In contrast to the classic MDLC, the two separation phases are located in a single biphasic column. Thereby, the eluted peptides from the SCX phase are directly trapped on the RP resin without any dead volume. Additionally, the system is simplified due to the location of the two phases in the ESI-tip emitter. The sample is bound on the SCX phase, and fractions are eluted by salt-plug injection. The fractions are trapped on the RP phase and

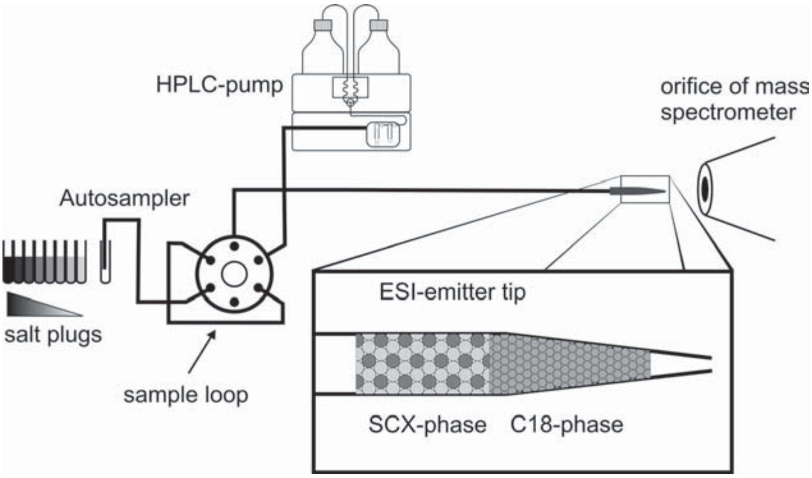

Figure 5.4-7. Schematic workflow of MuDPIT. The MuDPIT technique represents a relative simple setup compared with the other MDLC approaches. For the complete system, a single nano-gradient pump and an optional autosampler is required. The two-dimensional separation takes place in the biphasic ESI-Tip emitter, which results in a near dead-volume-free solution. Peptides are eluted from the strong cation exchange phase (SCX) with salt-plugs that are injected by the autosampler. Afterward the trapped peptides are separated with a linear gradient and directly sprayed into the mass spectrometer.

then separated by common RP gradients that are delivered by a single nano-HPLC pump. Therefore, the technical requirements are reduced in comparison with other online MDLC systems, and the complete separation is performed fully automated. The major disadvantage of this approach is the design of the biphasic separation column, because the two phases are in contact with a high salt concentration and high concentration of organic modifiers, respectively. This may lead to poor sample recovery and imminent loss of peptide species.

One major disadvantage of all presented approaches is the limited resolution in a two-dimensional separation. The discrete separation with tens of thousands of peptide species is still not possible. The combined fractional diagonal chromatography (COFRADIC) circumvents this problem by discarding most peptides [43]. The protein identification by MS requires only a single peptide that is specific for this particular protein. Therefore, the increase of sample complexity after enzymatic digest produces a lot of redundancy that is again reduced by the COFRADIC technique. The proteins are blocked at the cysteine and free amino-residues before proteolytic digestion. The resulting peptides are separated by RP chromatography and collected in minute fractions. Each fraction is then treated with TNBS to modify the newly generated free N-terminal amino groups and increase the hydrophobicity of these peptide species. Afterward, each fraction is rerun under the same conditions. All peptides that elute at the same retention time as before are original N-terminal peptides because they were blocked prior to TNBS-modification and are therefore not susceptible to retention time increase. These fractions can be collected for later MS analysis. The COFRADIC approach has also been extended to the separation of cysteine or methionine containing peptides [44]. Other targets

like phosphorylations or other moieties that can be chemical modified may be targeted as well. Therefore, the COFRADIC approach is very suitable for directed global analysis of specific peptide subsets in complex peptide mixtures.

5.4.4 SEPARATION OF PROTEINS

5.4.4.1 Short Introduction

RP–HPLC separates compounds based on the reversible interaction with the hydrophobic stationary phase. RP–HPLC has become the most extensively practiced type of chromatography for proteins due to the unparalleled resolution with applications in purification, desalting, and analysis.

RP–HPLC separation of proteins has been the topic of several reviews and book chapters, e.g., Refs. 45 and 46.

RP chromatography of proteins is almost exclusively dominated by gradient elution. Besides the ability of gradient elution to separate a complex mixture of compounds with a broad range of hydrophobicity, there is another reason for the almost exclusive use of gradient elution.

In contrast to small molecules, proteins are amphiphilic and interact with the stationary phase only via a small part of the molecule, whereas the hydrophilic parts of the protein are in contact with the mobile phase. The mobile phase at the start of the gradient is typically an aqueous solution. During development of the gradient, a protein will almost completely desorb from the stationary phase at a specific organic solvent concentration. Before this concentration, the protein has an almost infinite retention on the stationary phase and will therefore not migrate through the column. This principle, often referred to as "on/off" retention mechanism, is also indicated by the steep adsorption isotherms of proteins. As a result, closely related proteins can be separated by small adjustments in the mobile phase composition. Hence, isocratic elution of proteins is not an attractive technique.

5.4.4.2 Reversed Phase–Liquid Chromatography (RP–HPLC) Separation of Proteins

Liquid chromatography is an essential analytical tool for the separation of proteins in biotechnology and pharmaceutical product development. Applications are found throughout the development process of biological products, from drug discovery to quality control. Molecular properties of proteins, like molecular mass, net charge, hydrophobicity, and structure give ample opportunities to use HPLC for their separation.

A variety of chromatography techniques is available for separation and analysis of proteins, i.e., RP, IEX, size exclusion, hydrophobic interaction, and affinity chromatography. Selection of the type of chromatography, scale of operation, and applied detection technique will be based on the sample availability and complexity and, on the other hand, the required information.

Stationary Phases. The first step in the optimization of a chromatographic method for proteins is the selection of the stationary phase. Many stationary phases are

available and are characterized by the material, particle shape and size, pore diameter, and functional group. For analytical purposes, regular-shaped, silica-based stationary phase particles are mostly employed. These particles are made of alternating silicon and oxygen atoms that form an incompressible three-dimensional network. The surface of the silica particle is covered with hydroxyl groups, called silanol groups, which are modified with a reactive alkyl silane to yield a siloxane bond. The length of the alkyl chain, which can vary from methyl (C1) to octadecyl (C18), determines the hydrophobicity of the RP sorbent and the binding strength of the protein. Unreacted, residual silanol groups are present after functionalization of the silica bead and have acidic properties that impair the RP separation. Ionic interaction between these silanol groups and the protein result in low protein recovery and peak tailing. To overcome this effect, end-capping of the stationary phase can be performed, i.e., the reaction of residual silanol groups with a small molecule.

Another limitation of silica-based stationary phases is the limited pH stability, which extends from around 3.0 to 7.0. Acidic solutions hydrolyze the siloxane bond between the bonded alkyl silane and the silica particle; at high pH, the silica substrate is readily dissolved. The hydrolytic stability of RP silica particles can be improved by shielding the siloxane bond with bulky alkyl groups or by surface coverage of the silica with a highly cross-linked aromatic layer [47]. Organic polymer-based supports have been developed as an alternative for the inorganic, silica-based stationary phases and have a high pH stability.

Resolution of the protein separation is affected by several stationary phase properties. Reduction of the particle diameter is obviously the most straightforward way to improve the efficiency. For analytical purposes, 3- to 10-μm particles are a good compromise between chromatographic performance and the required pressure. The pore size of the particles should be a minimum of 300 Å to provide accessibility for large proteins.

The large size of the proteins implies that diffusion coefficients are low and that mass transfer between the mobile and the stationary phase is slow. Several stationary phases have been designed that prevent excessive band broadening as a result of the low diffusivity of proteins. Perfusion beads are highly porous particles made from polystyrene divinylbenzene with pore sizes in the range of 100–8000 Å. The structure allows the mobile phase to perfuse through the particles and a convective transport of the molecules, not limited by diffusion. The analysis time in perfusion chromatography can be reduced significantly compared with conventional stationary phases, due to the low flow resistance and independence of flow rate on the resolution [48].

On the contrary, particles without pores enable fast, efficient separation of proteins due to the absence of intraparticle diffusion resistance. The absence of pores reduces the available surface area and thereby the loading capacity. Silica- [49] and polymer-based [50] nonporous particles have been applied for biomolecule separations. Also hybrid particles have been described that have a non/porous core and a 0.25-μm porous layer, composed of colloidal silica particles [51].

The application of monolithic columns for efficient RP–HPLC separation of proteins is rapidly developing. The advantage of monolithic columns for protein separations is the high mass transfer efficiency due to convective flow in the macroporous structure. As a result, very fast separations can be achieved.

Several polymer-based monolithic columns have become available commercially in different formats, e.g., disks, membranes, and LC columns with diameters in the range of 0.1–100 mm ID [52]. The preparation and application of organic polymer-based monoliths have been reviewed recently [20].

Extremely rapid RP separations of proteins have been demonstrated on poly(styrene-co-divinylbenzene) monolithic columns. A fast gradient and a flow rate of 10 mL/min were used to separate five model proteins in less than 20 s on a 50 × 4.6-mm ID column [53].The same type of monolithic structure has also been prepared in capillary columns of 200 μm ID and showed excellent performance in the identification of proteins by LC–MS through peptide mass fingerprinting and accurate intact molecular mass determination [24].

Acrylate monomers are used for the preparation of monolithic columns and are available in a broad variety of chemistries. For the RP type of monolithic columns, acrylates with an alkyl chain are employed.

Poly(butyl methacrylate-co-ethylene dimethacrylate monolithic columns have been prepared by photoinitiated polymerization and used for RP–HPLC of proteins [54]. The flow resistance of these monolithic columns was low, which enabled the use of high flow velocities of 87 mm/s. A mixture of four model proteins ribonuclease A, cytochrome c, myoglobin, and ovalbumin was baseline separated in around one minute and using flow rates of 100 μL/min. In Figure 5.4-8, chromatograms are shown that were obtained with three different gradients.

No effect of the pore size in the range of 0.7–2.2 μm was measured on the retention of proteins.

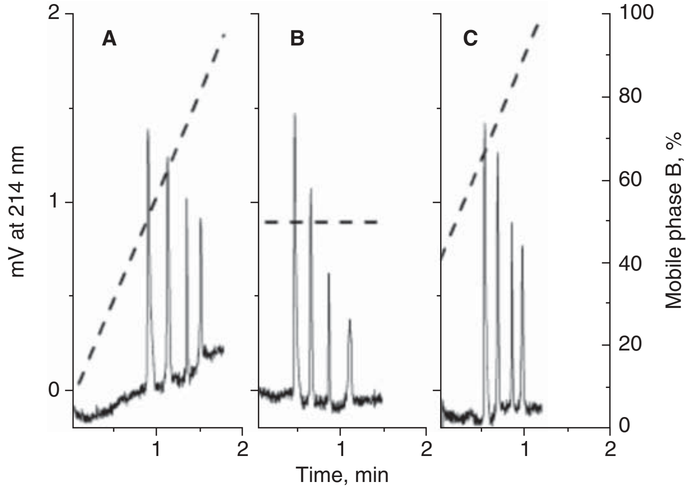

Figure 5.4-8. Effect of gradient on separation of a protein mixture using monolithic column I at 100 μL/min. Conditions: column size 100 mm × 0.2 mm. Mobile phase A, 0.1% TFA in water–acetonitrile (90:10, v/v); mobile phase B, 0.1% TFA in water–acetonitrile (10:90, v/v). Gradient in (a) 5–95% B from 0 to 1.8 min; gradient in (b) 5–50–50% B from 0 to 0.01 to 1.5 min, gradient in (c) 5–40–100% B from 0 to 0.01 to 1.21 min. Peaks: ribonuclease A, cytochrome *c*, myoglobin, and ovalbumin (elution order). (Figure and caption reprinted from Ref. 54, with permission from Elsevier.)

Mobile Phases and Gradients. Ion-pairing RP–HPLC is an ideal technique for the separation of proteins. A charged ion-pairing reagent with an opposite charge to that of the protein is added to the mobile phase to form a noncharged complex. The ion-pairing reagent increases the hydrophobicity and consequently the retention of the protein. TFA is the most commonly used ion-pairing reagent for proteins. Added in a concentration of 0.05% (v/v) to the mobile phase, the pH will be around 2.5. At this pH, the carboxylic groups of proteins are protonated and the trifluoroacetic anion binds to the protonated, positively charged amino groups of proteins.

Several ion-pairing reagents, including acids, bases, and salts, have been applied in RP liquid chromatography of proteins. TFA is preferred as it generally yields the highest separation performance. However, a disadvantage of TFA is that it can significantly lower the detection sensitivity in EIS–MS detection. The strong ion pairs are not easily broken apart under conditions used for EIS, thereby preventing ionization of the analyte. This effect is not easy predictable and has been found dependent on the ion-pairing reagent concentration, instrumental conditions, and the analyte. The influence of ion-pairing reagents on the sensitivity of detection in the coupling of RP–HPLC and ESI–MS for protein analysis has been reviewed [55]. In practice, a compromise between detection sensitivity and chromatographic resolution has to be found in the use of ion-pairing reagents for HPLC–ESI–MS applications. A more than 100-fold increase in detection sensitivity of proteins was reported when using 0.1% formic acid instead of 0.1% TFA at the cost of larger peak widths [56].

Several solvents can be chosen for the development of the gradient in RP chromatography. Acetonitril has a high volatility, low viscosity, and high UV transparency and is often preferred in LC/MS applications. For the analysis of large, hydrophobic proteins, alcohols with higher elution strength such as isopropanol can be employed. The gradient must be optimized for each application. Steep gradients are useful for protein desalting, whereas a shallow gradient should be used for complex samples.

Applications in Biotechnology. Biopharmaceutical products must be well characterized by means of analytical techniques. RP–HPLC with UV detection is suitable for the content assay and impurity profiling because of its high resolution. However, the bioactivity of protein-based pharmaceuticals not only relies on the primary structure but also on the higher order structure, i.e., the molecular confirmation, which is not revealed by UV absorbance. Circular dichroism and intrinsic fluorescence detection have been combined with UV detection in RP–HPLC to monitor the conformational properties of active compounds and impurities in biopharmaceutical products [57].

Characterization of (recombinant) proteins at the molecular level requires the use of MS detection.

RP–HPLC–MS can be applied to separate and identify proteins modifications such as deamidation, isomerization [58], and protein folding [59]. Even intact monoclonal IgG1 antibodies have been characterized by RP–HPLC–MS using a C8 stationary phase, elevated temperature of 65–70°C, and a combination of trifluoroacetic acid and heptafluorobutyric acid as ion-pairing agents.

Characterization of C-terminal lysine variants, glycosylation heterogeneity and degradation products of recombinant antibodies demonstrates the capability of this method [60].

The development of MS instrumentation has been accelerated during the last decade by proteomics research, the large-scale identification of the proteins in biological samples or tissues. Although nowadays the precise mass determination of even large proteins is possible on standard MS instruments, identification of proteins is still done at the peptide level after enzymatic digestion of the protein. An interesting development is internal gas phase protein fragmentation in the MS enabling accurate protein identification. In combination with a chromatographic separation, this development holds great promise for top-down proteomics [61].

5.4.4.3 Ion-exchange Separation of Proteins

In ion-exchange chromatography (IEC), retention is based on the interaction of charged amino acid residues of the protein with the counter-charge on the stationary phase media. In addition, protein modifications such as acetylation, phosphorylation, and glycosylation alter the charge of the protein and therefore the retention on the IEX column. IEX stationary phases carry either a positive charge (anion exchanger) or a negative charge (cation exchanger) and can be subdivided into weak and strong ion-exchanger resins. Strong ion-exchangers are ionized over a much wider pH range compared with their weak ion-exchanger and can be used over a broad pH range (~pH 2–12) Weak IEX columns lose their charge at pH > 9 (anion) and <6 (cation). The terms *strong* and *weak* do not refer to the strength of interaction; the interaction of the protein with the column is determined by the stationary phase, the mobile phase composition, and the protein. Elution of the protein is accomplished by competition with small counter-ions for the adsorption sites on the ion exchanger. Most often, linear salt gradients are used. Other means for protein elution are a pH gradient or a combined salt/pH gradient.

Method development is started with the selection of the type of ion-exchange resin and a buffer with appropriate pH to assure retention of the proteins to be separated. IEC separations are usually started with a low buffer and salt concentration with sufficient buffer capacity.

An advantage of IEC over RP–HPLC is that chromatographic conditions are very mild, thereby preserving the protein structure and bioactivity. Protein purification by means of IEC generally gives high yields and is an excellent technique for large-scale purification of pharmaceutical proteins in biotechnology.

Monolithic Columns for Ion-Exchange Chromatography of Proteins. Ionizable groups can be incorporated into monolithic structures to make them suitable for IEC in different ways. Starting with functional monomers has the advantage that the monolithic structure can be prepared in a single step. However, the process requires optimization for each new set of functional monomers and cross-linkers to obtain the required properties. Alternatively, the ionizable groups are introduced after the monolithic structure has been created in an additional step through reaction with the epoxide groups [62].

The epoxide groups of a polyglycidyl methacrylate-co-ethylene dimethacrylate monolith readily react with diethylamine to create a weak anion exchange column. This monolithic column is characterized by fast mass transport kinetics leading to excellent resolution. The columns seem to be stable, and the specific capacity is 40-mg/g medium for ovalbumin [60, 62]. More recently, graft polymerization within

the large pores of the monoliths has been used to attach chains of reactive polymer. The advantage of the grafting procedure is the high density of surface groups and consequently high binding capacities that can be achieved, which are favorable for the separation of biopolymers [20].

Application in Biotechnology. A high-performance anion-exchange chromatography method was used for the determination of erythropoietin (EPO) in pharmaceutical products [63]. EPO is a glycoprotein with a molecular mass of 30–34 kDa. Besides being the main factor regulating red blood cell production, it is known for extensive misuse as a performance enhancer in endurance sports. The content of EPO in pharmaceutical preparations is currently measured by complex *in vivo* potency assays.

It was shown that the chromatography method was suitable to separate recombinant EPO from amounts of human serum albumin commonly present as a stabilizer in various pharmaceutical preparations. In addition, it was possible to obtain different elution profiles for EPO products with variations in the glycoforms. Fluorescence detection was applied for quantification and showed linear signals over the range of 10–200-µg/mL EPO.

5.4.4.4 Multidimensional Liquid Chromatography of Proteins

In proteomics the sample complexity is often high and requires high-resolution analytical separation techniques. Two-dimensional polyacrylamide gel electrophoresis (2D PAGE) fulfills this requirement and has been established as a core technique for complex protein mixtures. However, the small dynamic range and the inability to resolve very small and large proteins and proteins with extreme pI values have been serious limitations.

Multidimensional liquid chromatography is becoming an attractive alternative to gel-based separations and has been reviewed recently [64]. The power of multidimensional techniques is the ability to increase the peak capacity significantly by adding selectivity to the system. From a theoretical point of view, the peak capacity of a truly orthogonal 2D-HPLC system, i.e., the nature of the separation principle of both dimensions are independent, is given by multiplication of the peak capacity of each dimension [65]. If the peak capacity of both columns is 50, the total peak capacity for the 2D-LC system will be 2500. However in practice, the resolving power of multidimensional LC techniques is impaired by limited orthogonality and the slowness of the second dimension separation.

A wide variety of separation mechanisms have been combined in 2D-HPLC to separate complex protein mixtures. Size exclusion [66], affinity [67], IEX [68–70], and chromatofocusing [71] have been used as a first-dimension separation in combination with RP as a second-dimension separation. IEX–RP, the most extensively studied combination, has been coupled to EIS time-of-flight MS for separation and identification of ribosomal proteins from yeast [72]. Approximately 70% of the potential ribosomal subunits isoforms could be identified with an average mass error of ~50 ppm. In the experimental setup, two parallel RP columns were alternately switched in series with a strong anion-exchange column to reduce the analysis time.

Distribution of proteins over multiple second-dimension fractions is unwanted and influenced by several aspects. Peak splitting is unavoidable and depends on the

elution profile and fraction size. In general, peak splitting can be worse for proteins with a molecular heterogeneity as a result of different modification forms or structural conformations. Also carryover or peak "ghosting" results in dispersion into multiple fractions and is generally more profound for high abundant and hydrophobic proteins.

The first dimension separation can be run with linear and step gradients.

An extensive comparison between these two gradient modes in IEX–RP separation of cytosolic proteins from *Escherichia coli* revealed a more effective fractionation for a linear salt gradient [70]. Fewer major proteins were distributed to multiple second-dimension fractions.

In the second RP dimension, gradient elution is required to elute proteins with a wide range in hydrophobicity. As gradient elution is typically a slow process, several approaches have been proposed to speed up the second-dimension separation, such as the use of short columns, high flow rates, and a parallel column setup [68].

Polystyrene–divinylbenzene monolithic columns have shown excellent separation performances for intact proteins [24]. A capillary PS–DVB monolithic column with 500 μm ID has been used in combination with IEX columns for offline 2D-LC of complex proteins samples. The power of this technique is illustrated with chromatograms of the separation of soluble proteins from *Salmonella typhimurium* in Figure 5.4-9. The ion-exchange separation has been developed on a strong cation- and anion-exchange column, coupled in series. The combination of these two IEX columns allow retention of both acidic and basic proteins. The resolution of the multidimensional separation is high. The PS–DVB monolithic column and IEX column have peak capacities of, respectively, 80 and 60. Giving the fact that 30 fractions were taken in the first dimension, the total peak capacity can be estimated as 2400 (80 × 30 fractions). The offline column configuration makes the method flexible; i.e., both dimensions can be optimized independently with respect to mobile phases, column dimensions, and sample loading.

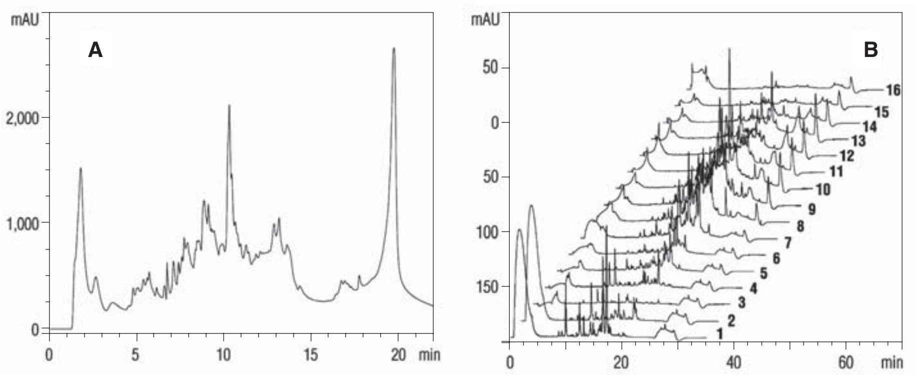

Figure 5.4-9. Offline 2D-LC of intact *S. typhimurium* proteins. (A) Separation of *S. typhimurium* protein extract on a ion-exchange ProPac SAX column. (B) Overview of the RP separations of Salmonella proteins on PS–DVB monolithic column 500 μm i.d. × 5 cm.

SEC. Another liquid chromatographic technique applied in biopharmaceutical characterization is SEC. In this technique, compounds are separated based on size and shape. In contrast to RP–HPLC, SEC has a low resolving power that has limited the application of the technique. The main application of SEC in pharmaceutical analysis is the determination of the native size of a protein and the quantification of protein aggregates. Typically protein-friendly conditions are employed in SEC that are expected not to affect the higher order structure of the protein.

5.4.5 SEPARATION OF AMINO ACIDS—AMINO ACID ANALYSIS

Amino acid analysis has become common in biotechnology, biomedical, and food analysis laboratories. In proteomics laboratories, this technique becomes now more important because quantitative proteomics requires knowledge about the exact sample amounts used in various kinds of experiments. Amino acid analysis is an exact, fast, and quantitative method for determining free and/or protein bound amino acids. Especially compared with Bradfort or Biuret, assays amino acid analysis is a more reliable technique with about an order-of-magnitude lower standard deviation. It is used to control protein yields from various protein preparations and to determine sample amounts prior to 2D-PAGE and 1D- and 2D-HPLC. Furthermore, it is necessary to measure exact protein amounts before stable isotope labeling with reagents like iTRAQ, ICPL, or ICAT [73–75]. If the ratio between chemical reagent and reactive side chain is chosen in the wrong way, a quantitative incorporation cannot be obtained and will lead to false results. Using relative quantification, the same protein amounts should be used. In the case of comparing sample A and B, the standard deviation will increase depending on the ratio of A to B and additional computation and data analysis are required to do normalization on the results.

Using the AQUA technology for absolute quantification of peptides from complex mixtures, it is mandatory to quantify the used stable isotope-labeled peptides before analysis, because peptides in solution undergo unspecific absorption to surfaces and will therefore alter their concentration [76]. However, even dried stable isotope-labeled peptides usually contain an amount of TFA salts from purification.

The method of choice to overcome these problems with the chemical quantification of proteins, peptides, or free amino acids are the classic amino acid analysis methods.

Amino acid analysis is an old method in protein chemistry (the first experiments were already described in 1820 by Braconnot). In 1972, Moore and Stein were awarded the Nobel Prize for establishing automated amino acid analysis. Roughly only two major methods for amino acid analysis exist: precolum derivatization and postcolumn derivatization. Today the sensitivity of amino acid analysis is at the femtomole level for fluorescence detection and at the picomole level for UV light detection methods. An overview about commonly used methods and reagents for amino acid analysis is shown in Table 5.4-2.

TABLE 5.4-2. Commonly Used Reagents for Amino Acid Analysis

Reagent	Method	Detection
Ninhydrin	Postcolumn derivatization	λ = 570 nm (prim. AA) λ = 440 nm (sec. AA)
Phenylisothiocyanate	Precolumn derivatization	λ = 245 nm
Orthophthaldialdehyde	Precolumn derivatization	λ = 338 nm
	Postcolumn derivatization	λex = 230 nm, 335 nm λem = 455 nm
Fluorescamine	Postcolumn derivatization	λex = 390 nm λem = 475 nm
Fluorenylmethylchloroformate (FMOC)	Precolumn derivatization	λ = 260 nm λex = 266 nm λem = 305 nm
6-Aminoquinolyl-N-Hydroxy succinimidyl Carbamate (AQC)	Precolumn derivatization	λex = 248 nm λem = 395 nm
Dabsylchloride	Precolumn derivatization	λ = 436 nm
Dansylchloride	Precolumn derivatization	λex = 310 nm λem = 540 nm

Abbreviations: λex = exitation wavelength; λem = emission wavelength.

5.5.1 INTRODUCTION

Before implementation of analytical methods for routine use, careful validation is required to demonstrate that the method is suitable for the intended purpose. Analytical methods employed for the quantitative determination of drug substances and their metabolites in biological media play a significant role in the evaluation and interpretation of pharmacokinetic data. To define the requirements and procedures for the validation of bioanalytical methods, a conference was held in 1990 in Crystal City in the Washington, DC, area, which was co-sponsored by the U.S. Food and Drug Administration (FDA), The Canadian Health Protection Branch, the American Association of Pharmaceutical Scientists (AAPS), and the Association of Official Analytical Chemists (AOAC), bringing together scientists from

regulatory authorities, industry, and academia [1]. Upon evaluation of the results of the first meeting, another conference was held 10 years later [2] that ultimately led to the publication of the FDA guideline “Guidance for Industry: Bioanalytical Method Validation” [3] complementing the general guidelines on method validation such as guidelines Q2A and Q2B by the International Conference on Harmonization (ICH) [4, 5] or pharmacopeial regulations [6]. From the beginning, it was realized that each analytical technique has its own characteristics, which will vary from analyte to analyte. Despite the fact that some similarities exist, a general difference between chemical methods, such as chromatography, and biological assays, such as immunoassays and microbiological assays, was acknowledged [1, 2].

Small, “conventional” drug molecules are preferentially analyzed by chromatographic techniques, specifically by liquid chromatography-mass spectrometry (LC-MS) and liquid chromatography-tandem mass spectrometry (LC-MS/MS), and, to date, most emphasis has been on the validation of bioanalytical methods for such molecules, which is also reflected in the FDA guideline [3]. However, because of the progress in recombinant DNA technology, the number of protein pharmaceuticals has increased dramatically. From 1996 through December 2005, the FDA has approved 253 so-called “biologics” for 384 indications [7]. Most of these products are proteins. As a result of their high potency and subsequent low applied doses resulting in extremely low concentrations in biological media, chromatographic techniques are not sensitive enough for bioanalysis. Thus, immunoassays are primarily used for the bioanalysis of protein drugs.

This divergence in analytical techniques for small molecules and macromolecules has triggered workshops and conferences on bioanalytical method validation of macromolecules focusing on issues such as quantitative immunoassays for therapeutic proteins, biomarkers, and drug neutralizing antibodies as well as bioassays. The results are documented in several publications of meeting reports [8–15], and these publications currently serve as quasi-guidance as no complete official document by the regulatory authorities of the United States or Europe on bioanalysis method validation of macromolecules exist to date. The FDA guidance on bioanalysis [3] acknowledges differences between the assay formats but does not cover all necessary topics for bioassays. A guideline by the European Agency for the Evaluation of Medical Products (EMEA) on pharmacokinetics of pharmaceutical proteins [16] also states specifics of immunoassays and lists points that should be addressed during method validation, but it provides no general guideline. Chromatographic assays are commonly applied to the analysis of protein drugs, but almost exclusively during product characterization release. Method validation of chromatographic techniques is basically identical for small molecules and macromolecules and is addressed in the ICH guidelines [4, 5], FDA guidelines [17], as well as in publications [18] and books [19, 20]. This chapter focuses on validation issues for macromolecule bioanalysis summarizing the current opinion according to the meeting reports [8–15] and further publications on method validation for macromolecules [21–25]. If possible, all terms related to assay validation are used in the sense of the ICH guideline Q2A [4]. A glossary of the most important terms is provided at the end of the chapter. A general guideline for method development of all different kinds of biological assays including validation aspects can be found on the Internet [26].

5.5.2 METHOD VALIDATION

Relevant macromolecular analytes in biological media can be classified into three categories: (1) pharmaceutical proteins administered as therapeutic agents; (2) biomarkers (i.e., endogenous substances that reflect physiological or pathophysiological processes or pharmacological responses to a therapeutic intervention); and (3) drug neutralizing antibodies that are generated as the response of the human organism to the application of a therapeutic protein. The primary assay formats for these molecules are ligand-binding assays (i.e., immunoassays and receptor-binding assays). Method validation of immunoassays will be the focus of the following discussion whereas cell-based assays will be only briefly addressed. Immunoassays can be roughly divided into competitive assays and sandwich assays, details are discussed in Chapter 5.3 of this volume. Validation will be discussed for immunoassays for the determination of pharmaceutical proteins in detail and, in subsequent sections, differences with regard to biomarkers and anti-drug antibodies will be mentioned. Not specifically addressed here, but evident in a good laboratory practice (GLP) environment, is the fact that proper documentation and standard operation procedures (SOPs) have to be written.

5.5.2.1 Ligand-Binding Assays

The term "ligand-binding assay" refers to methods that depend on the specific binding of an analyte to a biomolecule. Generally acknowledged inherent differences exist between bioanalytical chromatographic techniques and ligand-binding assays. The most relevant differences are summarized in Table 5.5-1. Whereas chromatography is based on physico-chemical principles, ligand-binding assays are based on a biological response because of the interaction of a ligand with an antibody or a receptor. Consequently, the reagents are derived from living organisms with the attendant variation typical for such reagents (i.e., poor batch-to-batch reproducibility). High-purity, well-characterized reference standards are most often not commercially available. Although specificity in chromatography is

TABLE 5.5-1. Comparison of the Characteristics of Chromatographic Assays and Immunoassays for Bioanalysis

Parameter	Chromatographic Assay	Immunoassay
Principle of measurement	physico-chemical properties of the analytes	antigen-antibody reaction
Detection	direct	indirect
Reagents, analytical standard	well characterized, high purity, widely available	not always completely characterized, unique, not widely available
Analytes	small molecules	small molecules and macromolecules
Sample pretreatment	typically pretreatment	usually no pretreatment
Calibration model	linear	nonlinear
Intermediate precision	high (<10%)	moderate (<20%)
Range	broad (several orders of magnitude)	limited

obtained by isolation of the typically small molecules from the matrix combined with analytical separation from other sample components and probably even detection by mass spectrometry, the isolation of macromolecules from biological media is impractical in most cases because of the low concentrations and the structural or physico-chemical similarity between the analytes and endogenous compounds. Thus, detection of the macromolecule analytes occurs in a complex physiological milieu and, therefore, highly depends on the specificity of the reagents and detection systems. Finally, whereas chromatographic assays display linear relationships between analyte concentration and detector response over a broad range covering 2–3 orders of magnitude, calibration curves of ligand-binding assays are typically nonlinear covering a rather limited range requiring dilution of very concentrated samples. On the time scale, the development of an immunoassay will be longer compared with high-performance liquid chromatography (HPLC) methods because of the need of the generation of antibodies. Once these antibodies have been obtained, the time frame for method validation between the assays is comparable. Sample throughput of immunoassays is excellent.

Standard Immunoassays. Validation is a continuing process through the whole life cycle of an assay. After selection of the assay format, preliminary data are obtained during method development, which are confirmed during prestudy validation and consequently applied during in-study validation (Table 5.5-2). This scenario is considered a “full validation.” Partial validation is conducted when changes of a fully validated method occur that are considered minor, such as changes in the anticoagulant or changes in the used reagents. Partial validation can range from a single intra-assay accuracy and precision determination to nearly full validation. Method transfer from the developing laboratory to another laboratory or a production site requires at least partial validation. Cross-validation is conducted when two or more validated bioanalytical methods are used within the same study. Test samples (spiked samples or incurred test samples) should be used and the data should be evaluated using appropriate predefined acceptance criteria. Some, but not all, validation issues have been addressed in the FDA guideline on bioanalytical method validation [3].

Assay Format. Assay format selection is the first step in method development. Assay formats include competition, sandwich, direct and indirect binding, inhibition, solid-phase, and solution phase assays. Reagents, first of all, include the antibodies; but diluents and additives such as detergents also have to be considered. For solid-phase assays, selection of the solid support as well as the chemistry used for the immobilization of the antibody may be critical. Consideration should also be given to the selection of the assay detection system to provide good signal-to-noise ratio. Detection may be improved by switching from colorimetric detection to fluorimetric or chemiliminescesence or, seldom, to radiometric detection. All these variables are evaluated during method development and confirmed during prestudy validation. In addition to the individual components, the manner in which an array is set up and run should already be considered during method development. The assay configuration (i.e., the number and placement of standards) of quality control (QC) samples, and study samples on a plate in an attempt to mimic the anticipated size of the run batches during routine use should be established as

TABLE 5.5-2. Validation Parameters

Parameter	Method Development	Prestudy Validation	In-Study Validation
Assay format	establish	confirm	apply
Reagent selection, stability	identify and establish	confirm	monitor, lot change requires confirmation of performance
Specificity and selectivity	establish	confirm	may not apply, confirm
Matrix selection	establish	confirm	monitor, changes in matrix require demonstration of comparability
Minimum required dilution	establish	confirm	monitor
Standard curve, calibrators	select model, establish	confirm	monitor
Assay range	evaluate	establish	apply
Dilutional linearity	evaluate	establish	monitor, establish for dilutions not covered in prestudy validation
Parallelism	not applicable	investigate when possible	establish with incurred samples
Precision and accuracy	evaluate imprecision and bias	establish imprecision and bias	total error (4–6–30 rule)
Sample stability	initiate	establish	continuing assessment
Robustness and ruggedness	evaluate	establish	monitor
Run acceptance criteria	not applicable	based on standard curve acceptance criteria	standard curve and QC acceptance criteria, apply 4–6–30 rule

early as possible and confirmed during prestudy validation. It is recommended that at least 5% of the total samples of a given batch consist of QC samples.

Reagent Selection and Stability. Probably the most critical components of the assay are the antibodies used. These antibodies are produced by living organisms with the inherent variability of such reagents. They must be acquired in adequate amounts and sufficiently characterized. As antibodies are prone to lot-to-lot variations, ideally, different lots are evaluated during method development and prestudy validation. When an antibody (reagent) lot has to be changed during routine application, in-study validation must demonstrate comparable performance of the lots.

Assay performance and sensitivity will deteriorate upon degradation of the antibodies and other reagents. Therefore, it is important to investigate storage conditions to ensure the integrity of key reagents for the estimated period of time that they will be used. Stability testing is not addressed in the regulatory guidance documents [3–5], but it is an important aspect of method validation. If

manufacturers provide expiration dates of reagents, they may be used instead of in-house stability determination. Reagent and antibody stability does not only concern storage at low temperatures (refrigerated or frozen), but standing times in laboratory equipment have to be considered. Thus, storage and handling conditions usually include bench-top stability, short-term and long-term storage, and stability to multiple freeze–thaw cycles. As it may also be desirable to store batches of assay microtiter plates for later use, the performance of a stored plate batch should be evaluated testing positive and negative samples. Stability is typically assessed during method development and confirmed during prestudy validation. It should be monitored during routine use.

Reference Material. In contrast to small molecules where reference standards are well characterized and certified standards are often commercially available from sources such as the U.S. Pharmacopeia, the European Pharmacopoeia, or the World Health Organization (WHO), proteins are often not as rigorously characterized and their purity may vary from supplier to supplier. Variation in posttranslational modifications such as glycosylation and deamidation may be present. Thus, the proteins can vary in their potency and immunoreactivity. As the reference compounds are used as standard calibrators, validation sample and QC sample variation of the reference will have a profound impact on the assay performance. Therefore, it is important to clearly document the source of the material and to characterize the proteins as thoroughly as possible. Comparability between lots or sources should be evaluated if possible. If the analyte is not a new drug entity, the innovator company is typically the most reliable source of authentic material. As stated for the reagents, stability of the reference compounds is an issue that has to be ensured.

Specificity and Selectivity. With regard to antibodies, specificity is the ability to specifically bind to the protein of interest in the presence of related endogenous and exogenous components (i.e., without cross reactivity). Selectivity, a related concept, describes the ability to determine an analyte in the presence of other constituents in a sample. Chromatographic methods are selective because they separate and detect analytes in a complex sample, typically after sample preparation steps for compound isolation. In contrast, ligand-binding assays measure analytes in biological matrices without prior isolation. Thus, high specificity may be desirable. With regard to interferences with other sample and matrix components and nonspecific binding of an antibody to such components, the terms “specific nonspecificity” and “nonspecific nonspecificity” are also used [9] sometimes as synonyms for the ICH terms. Specific nonspecificity is the interference caused by compounds with structural similarity to the analyte of interest. Such compounds may be metabolites, degradation products of the analyte, isoforms and variants with posttranslational modifications, as well as endogenous substances. Causes for nonspecific nonspecificity may be unrelated matrix components, (patho) physiological factors interfering with ligand binding such as serum proteins and lipids, hemolysis, or anti-IgG antibodies. In addition, nonspecific adsorption to the microtiter plate may occur.

As macromolecular analytes often have structural elements in common with endogenous compounds, specificity may be difficult to achieve. Variant forms of proteins may not be available at the time of method development. In such cases,

retrospective assessment may be acquired for the assay as more data become available over time. Rather than investigating specificity during method development, it is recommended to focus on reliable quantification of the analyte against a background of interfering matrix components [11].

Assay selectivity (nonspecific nonspecificity) is evaluated during method development by assaying spiked samples. Multiple lots of matrix should be evaluated, at least six [9] to 10 lots [11] are recommended. As selectivity problems occur, mostly at low concentrations, spiking should be performed at or near the lower limit of quantification (LLOQ). However, it may also be advisable to investigate higher concentrations. In case of interferences, it may be necessary to adjust the LLOQ before validation.

During prestudy validation, specificity and selectivity are confirmed. Selectivity may be expressed as acceptable recovery, applying the same principles as for the assessment of accuracy (see below). Acceptance criteria should be predefined. Acceptance criteria for selectivity and specificity typically do not exist for in-study validation. If potential interference may become a problem caused by the matrix from persons with the disease, specificity and selectivity should be confirmed by repeating suitable experiments once those disease-state matrices become available.

Matrix Selection. Matrix selection occurs in the development stage. Typically, biological fluids such as urine, plasma, serum, or cerebrospinal fluid as well as tissue samples may be collected. Additives such as anticoagulants, protease inhibitors, antioxidants, and so on may be present. It is necessary to document collection, processing, and storage conditions. The assay format may influence the choice of the matrix. For example, automated pipetting systems may be clogged by fibrin clots from plasma. In the absence of an endogenous signal, simple spike recovery experiments will determine the suitability of the matrix. In contrast, when the therapeutic protein is a recombinant version of an endogenous constituent, quantifiable amounts of the endogenous protein will be present in the matrix. Various strategies may be employed to limit or eliminate such interferences [9]. If the endogenous concentration is very low, and subsequently the percentage of the area under the curve obtained in pharmacokinetic studies caused by the endogenous compound is below 5%, the endogenous protein will introduce only a small bias and can be neglected. Alternatively, the endogenous level is determined from blank samples (no spike added) of a number of subjects and subsequently subtracted from the spiked samples. As already stated, 6–10 lots of the matrix should be evaluated. Further strategies include "stripping" of the matrix from the endogenous analyte either by nonspecific adsorption on charcoal or specific removal by affinity chromatography, the use of surrogate matrix from other species, or the use of protein-containing buffers. However, one has to keep in mind that the QC samples have to be prepared in the "original," unprocessed matrix. The presence or absence of matrix effects should be demonstrated by analyzing spiked samples at least at one concentration level. Differences between matrices obtained from healthy and diseased individuals may have to be considered.

In prestudy validation, the matrix selected during method development will be used to construct the calibration curves and validation samples. Once the effect of the matrix has been determined in method development, no further validation in later stages is required unless changes in the matrix occur.

Minimum Required Dilution. The minimum required dilution for an assay is the minimum magnitude of dilution of a sample with a defined diluent to optimize accuracy and precision in an assay. In many cases, dilution may not be necessary when analyzing plasma, serum, or other body fluids. Calibrator and validation samples are directly prepared in the matrix. For example, dilution may be required for samples with a background signal that is not caused by the endogenous version of the analyte. In the interest of a high signal-to-noise ratio (i.e., good accuracy and precision), sample dilution should be kept at a minimum. Once established during method development, this parameter should not be changed in later stages.

Assay Range. The assay range is defined as the validated concentration range between the LLOQ and the upper limit of quantitation (ULOQ), for which the results have an (predefined) acceptable level of precision and accuracy. The LLOQ and ULOQ are determined by the lowest and highest validation samples that show precision and accuracy of at least 25% expressed as relative error. The range is estimated during method development and validated by samples in the area of the anticipated LLOQ and ULOQ during prestudy validation. During routine use, samples that are above the ULOQ must be diluted (see "minimum required dilution" above). Samples that are below the LLOQ must be reported as "below LLOQ." The LLOQ during a batch run must be revised to higher concentrations if the QC samples at the lowest concentration fail to meet the 25% precision criteria.

Calibrators and Standard Curve. Standard calibrators are prepared by spiking known amounts of the (ideally, well-characterized) reference material into the matrix to obtain a standard curve from which the sample concentrations will be calculated. One of the major differences between chromatographic methods and immunoassays is that immunoassays display nonlinear relationships between the concentration and the measured response, which makes selection of the mathematical calibration curve model more complicated. Selection of the optimum calibration function is important to define the correct quantification range, to maximize accuracy and precision, and to achieve the quality control criteria. The mathematical model most widely used for immunoassay calibration curves is the four-parameter logistic function. If the curve is asymmetric, inclusion of a fifth parameter (i.e., using a five-parameter logistic function) may improve the fit to the data [25]. Algorithms that linearize the function such as logit-log may be used if goodness of fit is demonstrated, but such models are not recommended. Proper weighting of the data points in a calibration curve is also important to minimize bias and imprecision of the interpolated values near the LLOQ and ULOQ. Replicates with smaller variances are given greater weight compared with those with larger variances. The latter are normally found at the asymptotic ends of the curve [25].

As the standard concentrations should not be changed once validation has started, detailed investigation during method development is recommended using a greater number of data points and replicates compared with later validation stages [9, 11]. In the method development phase, the calibration curve should be constructed from a minimum of 10 non-zero standard points in duplicate spanning the anticipated concentration range about equally spaced on a logarithmic scale. Curve

fit is achieved by a four-to-five-parameter logistic function. Whether to weight or not weight the responses should be supported by an evaluation of the relationship between the standard deviations of replicate values and the mean values at different concentration levels [25]. A minimum of three independent runs should be used to establish the calibration model with duplicate curves included in each run to estimated intrabatch standard curve repeatability. The absolute relative error for back-calculated standard point should be ≤20% ("intracurve"). Acceptability of a model is verified by evaluating the relative error (relative bias) between back-calculated and nominal concentrations of the calibration samples. A model is considered acceptable if the relative error for all back-calculated standard points does not exceed 10% ("intercurve") and the precision (coefficient of variation) for each calibrator is ≤15% [11]. Lack of fit may be caused by the use of an inappropriate mathematical function such as applying a four-parameter logistic function to asymmetric curves or inappropriate weighting of calibrators.

During prestudy validation, a minimum of six non-zero standards in duplicate are spaced evenly on the logarithmic concentration scale to fit the four-to-five-parameter logistic function. At this point, additional calibrators outside the range of quantification (so-called "anchor points") may be included to facilitate curve fitting. This approach is in agreement with the FDA guidance on bioanalytical method validation [3]. The regression model should be confirmed using at least six independent runs. Typically, the same runs are used to determine accuracy and precision (see below). For acceptable curves, the back-calculated values for at least 75% of the standard points not including the anchor points should be within 20% of the theoretical value (except at the LLOQ, where 25% are acceptable), and upon completion of the validation, the cumulative relative error and coefficient of variation for each calibrator should be ≤15% and ≤20% at the LLOQ.

The standard curve should be monitored during in-study validation with at least one set of calibrators per patch run. As for prestudy validation, the curve should be constructed from six concentrations in duplicate. Anchor points may be used. The final number of points used for curve fit must be either 75% of the total number or a minimum of six calibrator samples not including the anchor points. The relative error of the back-calculated samples should be ≤20% (≤25% at the LLOQ). If either the high or low calibrator standards have to be deleted, the range for this particular run must be limited to the next standard point. Samples out of range must be repeated.

Precision and Accuracy. Precision and accuracy are assay performance characteristics that describe the random (statistical) errors and systematic errors (bias) associated with repeated measurements of the same sample under specified conditions [3–5]. Precision is typically estimated by the percent coefficient of variation (% CV, also referred to as relative standard deviation or RSD) but may certainly also be reported as standard deviations. Method accuracy is expressed as the percent relative error (% RE) and is determined by the percent deviation of the weighted samples mean from samples with nominal reference values. A collection of validation sample statistics can be found in References 9, 11, and 25.

Spiked samples are analyzed over multiple runs with replicate determinations during method development and prestudy validation. QC samples are used during in-study validation to monitor the performance of the assay. Limits for minimum

acceptable precision and accuracy should be established before or during method development and used throughout the life cycle of the assay.

It is recommended to determine accuracy and precision during method development with at least three batch runs using a minimum of eight sample concentrations analyzed in duplicate. The concentrations should span the whole validation concentration range of the assay. Recommended target limits for intrabatch and interbatch precision (% CV) are ≤20%, bias (% RE) should not exceed ±20%. At the LLOQ, a maximum of 25% for % CV and % RE is acceptable. These values are more lenient compared with the typical target values of chromatographic assays (% CV; 15% and 20% at LLOQ [3–5]) because immunoassays are inherently less precise than chromatographic assays [27]. In prestudy validation, at least six batch runs with a minimum of five different concentrations, one at the LLOQ, one at the ULOQ, and three concentrations in the lower, medium, and high range, analyzed in duplicate should be used for accuracy and precision determination. For each validation sample, the repeated measurements from all runs have to be statistically analyzed together. The target values for intrabatch and interbatch precision as well as accuracy (bias) are the same as the values applied in method development (20%, except for LLOQ, where 25% is acceptable). The total error of the method (i.e., the sum of % RE and % CV) should not exceed 30% (40% at the LLOQ). Further, for each in-study run, precision and accuracy are monitored by QC samples. Recommended run acceptance criteria are based on the total error, specifically on the deviation of the measured values from the nominal values, and not on statistical calculations such as the means or standard deviations. As QC samples, one set of at least three concentrations, one each in the low, medium, and high concentration range, are analyzed in duplicate in each batch run. As for small molecules, at least two thirds of the measured values of the QC samples must fall within a certain percentage of the corresponding nominal values and at least 50% of the results for each concentration of the QC samples must be within the specified limit. Thus, not all samples of a specific concentration are allowed outside the specifics. For chromatographic assays for small molecules, 15% has been adopted as limit (i.e., the "4–6–15 rule") [2]. At the LLOQ, 20% are acceptable. As a result of the lower precision of immunoassays, the error margin has been widened, a 6–4–25 rule is recommended by Findley et al. [9], whereas a 4–6–30 rule has been proposed at the macromolecule bioanalysis workshop [8]. The 30% margin is identical with the maximal acceptable total error of the method (sum of % RE and % CV) of the prestudy validation. Other statistical methods as acceptance criteria have been published [9, 28, 29] and can also be applied.

Dilutional Linearity. As the range of an immunoassay is usually limited, it may be necessary to dilute concentrated samples. Therefore, it has to be demonstrated that the analyte can still be reliably quantified upon dilution of high concentration samples so that they fall within the validated range of the assay. Moreover, a so-called prozone or "hook effect" can be identified. A hook effect is present when high concentration samples above the ULOQ display a lower response than ULOQ samples because of signal suppression caused by the high concentration of the analyte [30]. Dilutional linearity should not be confused with parallelism (see below).

Dilutional linearity is evaluated during method development, typically with spiking 100-fold to 1000-fold greater concentrations into the sample matrix

followed by dilution with the assay matrix. Dilutions should be made so that several dilutions fall within the standard curve in the lower, middle, and upper parts of the curve. Dilution samples above the ULOQ can be included to evaluate a hook effect. The dilutions are further confirmed during prestudy validation. The back-calculated concentration for each diluted sample should be within 20% of the nominal or expected value. The precision of the cumulative back-calculated concentration should be ≤20%. If a sample has to be diluted during routine use of the method to a higher extend than assessed during prestudy validation, dilutional linearity should either be repeated or a dilutional QC sample should be included in the assay.

Parallelism. Parallelism is a characteristic that is typically assessed during in-study validation. It is conceptually similar to dilutional linearity with the difference that it is determined by dilutions of actual study samples (incurred samples). In some cases, samples from a preclinical pilot study may be available during prestudy validation so that assessment of parallelism may be performed at that time. Moreover, when an assay is validated with the aim to replace another assay, incurred samples from a previous study may be available for evaluation of this performance characteristic.

Parallelism is assessed using C_{max} samples from an actual study. Commonly, samples from several individuals are pooled to create a suitable validation sample. Using pooled samples eliminates the need for generation of multiple values for individual study samples. It is recommended that the relative standard deviation between samples of a dilutional series should be ≤30%.

Sample Stability. Experiments demonstrating sufficient stability of the analyte in the sample matrix must be included in prestudy validation. Such experiments should mimic as closely as possible the conditions under which study samples will be collected, stored, and processed. Assessment should include bench-top stability, refrigerator stability, whole-blood stability, freeze–thaw stability, and long-term freezer stability. Stability samples can be prepared by spiking the analyte reference at high and low concentrations into the sample matrix.

Bench-top stability refers to the conditions under which the samples are handled during processing of the samples at the analytical site and should be examined at room temperature for at least 2h and at 2–8°C (refrigerator temperature) for a minimum of 24h [31]. The stability in whole blood can be determined by spiking the analyte into freshly collected whole blood followed by incubation for up to 2h and processing to obtain plasma or serum samples at certain intervals. The samples are subsequently processed and analyzed [31]. Typically, freeze–thaw stability evaluation includes three freeze–thaw cycles with at least 12h between the thaws. The rate of freezing and thawing should mimic the manner in which samples will be handled as they are thawed before the assay. Long-term stability should demonstrate that the samples are stable throughout the lifetime of the study. The necessity to conduct studies on samples stored at −20°C and −70°C to −80°C may depend on the duration of the study.

Assessment of the stability is typically performed during prestudy validation and continued during in-study validation. If changes in sample handling or storage occur, additional stability evaluations must be carried out to reflect the altered conditions. The acceptance criteria for the stability evaluations, with the exception of the whole-blood stability, will be the same acceptance criteria applied for

accuracy and precision of QC samples. If the measured value is within the acceptance criteria for accuracy, the sample is considered stable.

Robustness and Ruggedness. Robustness is the ability of an assay to withstand small but deliberate changes that may affect the assay. Such factors may, for example, include incubation temperature and duration, number of washes, light exposure, and lot-to-lot differences in key assay reagents or microtiter plates. Changes that may have an impact on the assay have to be clearly identified in the method description (SOP). The term ruggedness is not mentioned in the IHC guidelines [4, 5], but it is included in the USP monograph on validation [6]. The term describes the consistent performance of an assay under routine changes (i.e., different analysts, instruments, batch size). Such changes should have no significant impact on the consistency of an assay.

The extent of the assessment of robustness and ruggedness depends on the anticipated application of the method, the current status of the assay's life cycle, industry standards, and, last but not least, common sense. The majority of robustness testing will be conducted during method development to facilitate the early identification of factors that affect assay performance. Prestudy robustness and ruggedness validation may be limited to the conditions demonstrating acceptable performance under the anticipated in-study conditions, such as incubation temperature and time tolerances, batch sizes, and so on, but more formal evaluation can also be applied. Acceptable robustness and ruggedness during routine use are assumed when monitoring in-study QC samples demonstrating acceptable intra-assay and interassay precision.

Run Acceptance Criteria. Run acceptance criteria are used to accept or reject a run because of its performance. As a consequence, no defined run acceptance criteria are applicable during method development. Prestudy validation runs are accepted based on the standard curve acceptance criteria. No run can be rejected because of poor performance of a sample during precision and accuracy evaluation; all data from prestudy validation runs are reported unless there has been a clearly recognizable error during sample preparation or measurement. Despite the fact that the standard curve must satisfy the criteria described for standard curves above, in-study runs are accepted based primarily on the performance of the QC samples. As stated above in the paragraph on precision and accuracy, the 4–6–30 rule is recommended (i.e., at least four of six QC samples must be within 30% of their theoretical values and at least 50% of the values for each level must satisfy the 30% limit.

Biomarker Assays. A biomarker is defined as an endogenous substance that reflects physiological or pathophysiological processes or pharmacological responses to a therapeutic intervention [14], with a few exceptions such as viral load biomarkers are endogenous substances. It is a diverse class ranging from electrolytes to small molecules and macromolecules and a wide variety of analytical methodologies is used to quantify such substances. Although many assay characteristics apply to other analytical techniques and analytes as well, the following discussion will only touch on ligand-binding assays for the determination of macromolecules. As for the bioanalysis of therapeutic proteins, no official guidance documents are currently

available for biomarker analysis. Moreover, differences exist between validation approaches according to GLP regulations, which are the basis for documents of the FDA and other regulatory agencies and the National Committee for Clinical Laboratory Standards (NCCLS) guidelines for diagnostic assays. Details can be found in References 13–15; the present discussion will only include the parameters used in a GLP regulatory environment.

Besides, in clinical diagnostics especially, novel biomarkers play an increasing role in drug development for the investigation of the pharmacologic response to drug treatment or as surrogate markers for clinical endpoints. Clinical and drug development decisions will depend on the quality of biomarker data. Thus, the utility and value of such data is ultimately determined by the validity of the assay and requires demonstration and documentation of performance characteristics, as mentioned in the previous subsection, for immunoassays such as accuracy, precision, specificity, range, stability, and so on. However, in contrast to bioassays for drug compounds, where quantitative results are achieved by calibration typically using well-defined reference standards, biomarker assays may differ considerably depending on the type of analytical measurement, the type of the analytical data that develop from the assay, or the intended use of the assay. Subsequently, different assay types and validation levels may apply. Rigorous method validation for a novel biomarker is not necessary for drug discovery-phase work. However, the design of the validation must change when the assay is transferred from screening to quantitative determination in later phases of drug development.

Biomarker assays (as other bioassays) may be classified into "definitive quantitative assays," "relative quantitative assays," "quasi-quantitative assays," and "qualitative assays" with varying degrees of validation requirements (Table 5.5-3) [14, 15]. For definitive quantitative assays, a well-defined or characterized standard of the biomarker is available. In the case of relative quantitative assays, calibration is performed with a standard that is not well characterized, not available in pure form, or not representative of the endogenous biomarker. Results from these assays are

TABLE 5.5-3. Assay Categories and Validation Characteristics

Parameter	Definitive Quantitative Assay	Relative Quantitative Assay	Quasi-Quantitative Assay	Qualitative Assay
Accuracy	✓	✓	—	—
Precision	✓	✓	✓	—
Sensitivity	✓ (LLOQ)	✓ (LLOQ)	✓	✓
Specificity	✓	✓	✓	✓

Parallelism	✓	✓	—	—
Standard and reagent stability	✓	✓	—	—
Matrix stability	✓	✓	✓	✓

expressed as numerical values. Currently, most biomarker assays fall into the relative quantitative category. In quasi-quantitative assays, no reference material is available for the construction of a calibration curve. Nevertheless, the analytical result is expressed in numerical units. Examples are the measurement of enzymatic activity (expressed as units per volume) and vaccine or anti-drug antibodies where the response is reported as percent binding or titer. Qualitative assays use no standard either, and the results are reported non-numerically (i.e., "low, medium, and high" or "+, ++, and +++").

Although with respect to validation criteria a lot of similarities exist between ligand-binding assays for pharmaceutical proteins and biomarker assays, significant differences have to be noted, especially for novel biomarkers, in which a suitable reference standard is not present. If the intended reference is a recombinant protein, one should keep in mind that such proteins often have glycosylation patterns different from the endogenous equivalents. The glycosylation pattern of endogenous proteins is often heterogeneous so that it is virtually impossible to prepare glycoprotein standards that are identical to the natural circulating proteins. In the ideal case, a purified endogenous protein from the target species is used as a reference. This standard should be characterized in terms of analytical purity as thoroughly as possible. If a well-characterized standard is not available, the assay results will provide rather "relative" than "true" numerical values. As a result of the presence of endogenous biomarkers, no analyte-free matrix exists for the preparation of calibrator standards, which makes the establishment of the LLOQ particularly challenging. Standard curves may be prepared using pooled matrix from individuals with low baseline concentrations of the compound. Alternatively, (affinity) stripped matrix, a protein-containing buffer or matrix from an alternate species with negligible concentrations of the analyte, may be considered. Further strategies for minimization of interference from endogenous biomarkers can be used [9]. The preparation of calibrator standards not in the actual sample matrix is one major difference of biomarker assays from assays of protein drugs. When using such approaches, it has to be ensured that the use of the surrogate matrices does not introduce a bias in the assay. In contrast to calibration samples, QC samples must be prepared in an authentic matrix. In this case, matrix samples containing low basal levels can be selected and the middle and upper QC concentrations can be prepared by the addition of known biomarker amounts. Moreover, the disease state can have an impact not only on endogenous biomarker levels but also on the composition of the matrix itself. High concentrations of the marker produced during disease can cause a hook effect. A disease state may also alter the heterogeneity of the biomarker with altered cross reactivity to the antibody relative to the standard. The modified matrix composition can result in increased nonspecific binding (i.e., nonspecific nonspecificity).

The stages of validation of biomarker assays include establishment of the biomarker (development), so-called prevalidation, prestudy validation, and in-study validation [13–15]. The following short discussion will focus on the "GLP-like" definitive and relative quantitative assays. As the development and validation of an assay for novel biomarkers is quite diverse, the application of strict validation procedures appears problematic. Therefore, upon establishment of the prototype assay in the development phase, a formalized validation plan should be developed that

defines the scope and purpose of the assay. Further activities during method development include the establishment of the reference standard, selection of antibodies and the assay format, as well as evaluation of key reagents. As mentioned above, selection of the matrix for the preparation of the calibrator concentrations may be challenging because of the presence of endogenous biomarker. Subsequently, the calibration curve model will be established. As for other immunoassays, nonlinear calibration using the four-to-five-parameter logistic model is the commonly acknowledged model for data fitting.

The prevalidation phase may be regarded as a method optimization phase where the calibration model is confirmed; range, LLOQ, and ULOQ are defined; and matrix interference is evaluated. The use of anchor points for the calibration curve may be feasible. As mentioned above, determination of the LLOQ may be difficult because of the presence of the endogenous analyte. Dilutional linearity may be evaluated as well. It is also considered useful to assess the biomarker in healthy and diseased individuals. For this purpose, at least 25 individuals should be tested [9] to account for intrasubject variability caused by circadian and seasonal fluctuations and intersubject variability.

Prestudy validation will additionally evaluate standard and reagent stability as well as matrix stability during collection processing and storage of the samples, will determine dilutional linearity and parallelism, and will confirm assay range and the calibration model. These criteria can be determined as described for immunoassays for pharmaceutical proteins above. In addition, accuracy and precision have to be determined. It is recommended to use validation samples at five different concentration levels analyzed at least in duplicate and in a minimum of six runs. One concentration should be at the anticipated LLOQ, one about 2–4 times the LLOQ, one in midrange on the log scale, one about 70–80% of the anticipated ULOQ, and one at the anticipated ULOQ. The following method acceptance criteria have been recommended [14]: Both accuracy (% RE) and precision (% CV) should be within 25%, except at the LLOQ where 30% is acceptable. Even more lenient criteria may be required in some cases, depending on the analyte or the type of assay and its limitations. It is important to note that such QC samples must be prepared in the actual matrix. The use of buffer, surrogate, or stripped matrix is not feasible, except for rare matrices such as cerebrospinal fluid or tears, where a surrogate matrix may be the only practical option. Spike recovery experiments should be performed on multiple individual lots of matrix to assess the accuracy, matrix effects, and interference. It may also be favorable to include a pilot study into prestudy validation runs.

As for immunoassays for pharmaceutical proteins, in-study validation of biomarker assays should include one set of calibrators to monitor the standard curve as well as a set of QC samples at three concentrations analyzed in duplicate for the decision to accept or reject a specific run. Recommended acceptance criterion is the 6–4–30 rule, but even more lenient acceptance criteria may be justified based on statistical rationale developed from experimental data [14].

Anti-drug Antibody Assays. Basically, the protein sequence of biophar-maceutical therapeutics can be nonhuman, chimeric, humanized, or fully human. Most such therapeutics elicit some level of antibody response against the product leading to

potentially serious side effects or loss of drug efficacy. Thus, the immunogenicity of therapeutic proteins is a concern for clinicians, manufacturers, and regulatory agencies. For the detection of anti-drug antibodies, a number of assay methods including enzyme-linked immuno-sorbert assays (ELISA), immunoblotting, surface plasmon resonance, and bioassays are available, each technique having its own advantages and disadvantages [24]. Whereas binding assays identify the antibodies, immunoblotting provides information on the specificity. Surface plasmon resonance can show the antigen-antibody interaction in real time, whereas bioassays demonstrate the neutralizing potential of the antibodies. To date, microtiter plate-based ELISAs are still the most widely used format for testing for anti-drug antibodies because of their simplicity, sensitivity, and high-throughput capability. Generally, the validation parameters outlined for standard immunoassays as required by the regulatory authorities apply to immunoassay-based anti-drug antibody assays as well. These parameters include specificity, selectivity, accuracy, sensitivity, precision, robustness, ruggedness, and stability of reagents, analyte, and matrix. However, some differences exist because of the nature of the antibodies. These differences will be briefly addressed below. Further details can be found in References 22–24.

As a result of the lack of reference material, anti-drug antibody assays are generally quasi-quantitative assays (Table 5.5-3). In addition, the target analyte is generally polyclonal, consisting of antibodies of various isotype classes, specificities, and affinities (i.e., the analyte is not a defined molecule). Thus, no single positive control exists that accurately represents the target analyte. During the early validation phase, no clinical studies have typically been performed, so it may be a challenge to obtain a representative positive sample for method development and validation. When establishing specificity, accuracy, and sensitivity, several control analytes from different individuals or sources representing the test population should be investigated. Specificity of analyte binding can be assessed using immunodepleted samples.

Selectivity is a critical parameter determining the reliability of an antidrug antibody assay. In this context, one has to keep in mind that selectivity can vary between test samples because of the heterogenous nature of the antibodies. For the evaluation of selectivity, immunoglobulins and other potential interfering substances can be spiked into positive and negative samples at high but physiologically relevant concentrations. No substantial interference can be concluded if the recovery is 80–125%. The influence of different sample matrices, typically serum and plasma, should also be evaluated if both matrices may be analyzed with the same assay. The type of the matrix should not change the outcome of the assay. Furthermore, a comparison of specificity between normal- and disease-state matrices should be conducted to detect interfering substances that may be present in certain populations or disease states. Another unique property of anti-drug antibody assays is that the drug itself can act as an interfering substance, which can be mimicked with addition of the drug in varying concentrations to positive controls.

As a result of the quasi-quantitative nature of anti-drug antibody immunoassays and the lack of a reference standard a threshold value, the so-called “cutoff” or “cutpoint” is used to identify positive samples from nonspecific background noise. The assay cutoff is preferably determined by analyzing samples from healthy individuals and those affected by the disease. The data are subsequently used to

calculate the cutoff value yielding 5% of false positives [23]. Moreover, one should consider that a low optical readout increases imprecision so that the cutoff level should not be too low for optical assays.

The sensitivity of an immunoassay is typically defined by its LLOQ, which can only be determined when a reference standard is available. Alternatively, a detection limit of qualitative assays is used where a distinction is essentially made between positive and negative results only. Typically, the antibody data are reported as "titer," the titer being the reciprocal of the highest dilution of a sample in which the instrument response is greater than the cutoff response [22]. At least two positive control analytes should be used. If a positive control antibody is available, a pseudo-calibration curve can be generated by a series of dilutions. However, one should keep in mind that "true" quantitation is impossible because of the lack of a true reference compound. Determination of the dilutional linearity is not so important when the result is reported as a titer. However, if the determination of positive samples is based on the interpolation from a reference standard curve, it is essential to demonstrate that the QC samples fall within the (limited) linear range of the calibration curve and not on a plateau or a region that may include a hook effect.

Precision should be assayed using positive controls, negative controls, and a diluent sample. Positive controls should be prepared at a high and a low concentration to demonstrate precision within this assay range. Typically, precision (% CV) of ≤30% is considered acceptable [22]. In-study monitoring of a batch run using QC samples consisting of at least one positive control, a matrix negative control, and a diluent negative control should be used to estimate assay performance.

5.5.2.2 Validation of Cell-based Bioassays

Bioassays use living systems that measure the biological activity of a therapeutic agent. Such assays may be used to study the effects of hormones or growth factors, but such systems can also address drug toxicity and side effects. Moreover, bioassays may also be applied to bioanalysis of biopharmaceutical proteins. Only *in vitro* assays using cell culture systems measuring a discrete response such as cell proliferation, differentiation, or survival will be briefly addressed. Bioassays may generate quantitative or quasi-quantitative data. Only a few considerations for bioassay method validation will be mentioned, as this type of assay is not frequently applied. Most validation procedures for quantitative assays, such as calibration and reagent and matrix stability, accuracy, and precision, are essentially identical to the procedures described for standard immunoassays above.

For a validated assay, an established immortal cell line is typically used. Thus, during method development, not only must a suitable reference standard be established, but also documentation of the cell line with respect to characteristics such as origin of the cell line, culture and passage history, morphology, surface markers, and receptors is required. It is advisable to study the effect of cell age (number of passages) on the measured response. Specificity may be another issue as cell lines proliferate, differentiate, or senesce and die in response to a large number of biomolecules that may be present in the samples obtained for bioanalytical studies. In addition, macromolecules can be metabolized leading to metabolites that may also be biologically active, which is not relevant when a pure compound is applied to the cell culture to study its effect on the cells. However, bioanalytical methods based on

bioassays may not be specific for the analyte of interest. In this case, extensive study of interference because of nonspecificity should be conducted during prestudy validation using samples from a number of representative individuals.

5.5.3 CONCLUSIONS AND FUTURE CONSIDERATIONS

Despite the wide availability of chromatographic techniques hyphenated to mass spectrometry, immunoassays remain the most important methods for bioanalytical applications for monitoring macromolecules such as therapeutic proteins, biomarkers, or drug-induced antibodies. Current guidelines of regulatory authorities focus on chromatographic techniques with no or little reference to the specifics of ligand-binding assays. As some differences with respect to assay validation exist between chromatographic and ligand-binding assays, a number of issues require special attention. Reference material of the target analyte(s) is not always available in pure form, which is especially true for biomarkers and anti-drug antibodies. In addition, key reagents such as the antibodies for the immunoassay are frequently not commercially available. Stability issues of those key reagents, the reference material, and the biological matrix have to be considered.

The calibration curves of immunoassays are nonlinear, so that special attention should be paid to the selection of the correct calibration model. Anchoring points out of the validated range may optimize the curve fit. Selectivity of an immunoassay depends on the specificity of the antibody directed toward the analyte. Nonspecific interferences from the matrix as well as specific interferences (cross reactivity) from related compounds have to be considered. Special challenges occur if the analyte is an endogenous compound. In this case, analyte-free matrix may not exist, so that alternative strategies for the preparation of validation samples have to be explored. However, QC samples should be prepared in the original matrix if possible. Pathological states may alter the composition of the matrix or, in the case of biomarkers, the respective concentration, which has to be considered for an appropriate selection of the calibration standards and QC samples. Assays for anti-drug antibodies are quasi-quantitative so that complete GMP-like validation is normally not possible. Finally, as ligand-binding assays are inherently less precise than chromatographic assays, more lenient acceptance criteria for accuracy and precision as well as for run acceptance should be applied. The current opinion according to conference reports recommends as target values for precision (expressed as % CV) and accuracy (expressed as % RER) a maximum of 20% (25% at the LLOQ). Despite known disadvantages, application the 6–4–30 rule as run acceptance criteria during in-study validation has been adopted.

The current gap between the need for validated immunoassays according to GLP compliance and the lack of official guidance documents will certainly be closed in the near future because ongoing efforts at conferences between scientists from regulatory authorities, pharmaceutical companies, and scientific organizations will ultimately result in such guidance documents. However, technological advances in instrument automation and new technologies will continue to create new issues that have to be considered when developing and validating methods for bioanalysis. As each technique has and will have unique features, the challenge is the implementation of a dynamic, yet standardized and systematic approach for analytical method validation.

5.5.4 GLOSSARY OF VALIDATION TERMS

The terms are used according to the ICH guidelines [4, 5], where indicated, or according to the FDA guideline [3].

Acceptance criteria: Numerical limits, ranges, or other suitable measures for the acceptance of the results of analytical procedures.

***Accuracy* (ICH)**: The closeness of agreement between a measured value and the theoretical true value. In statistics, accuracy is typically reported as % relative error (% RE).

Batch: A set of standard curve calibrators, validation samples or QC samples, or study samples that are analyzed in a single group of measurements; it is synonymous with run.

Bias: Systematic difference between measured test results and the theoretical true value. Bias is expressed as relative error (% RE) or as a ratio (% recovery).

Calibration curve: The functional relationship between the analyte concentration in standards (calibrators) and the measured response; it is synonymous with standard curve.

Calibrator: A solution of a biological matrix spiked with the analyte of interest for the construction of calibration curves; it is synonymous with standard.

Dilutional linearity: A condition where a spiked sample is serially diluted to result in a set of samples containing analyte concentrations that fall within the quantitative range of the assay and the whole set of dilutions can be measured with acceptable accuracy. Dilution of the sample does not result in biased measurement of the analyte concentration.

***Intermediate precision* (ICH)**: Precision within a laboratory: different days, analysts, equipment, and so on.

Lower limit of quantitation (LLOQ): The lowest concentration of an analyte in a test sample that can be determined quantitatively with suitable accuracy and precision (ICH term: limit of quantitation).

Parallelism: A condition where spiked (calibrator) samples are serially diluted to result in a set of samples having analyte concentrations that fall within the quantitative range of the assay and do not exhibit an apparent trend toward increasing or decreasing estimates of the analyte over the range of dilutions.

***Precision* (ICH)**: The closeness of agreement (degree of scatter) between a series of measurements obtained from multiple sampling of the same homogenous sample under defined conditions. Precision is considered at three levels: repeatability, intermediate precision, and reproducibility. In statistics, precision is typically reported as % coefficient of variation (% CV), also referred to as relative standard deviation (RSD).

Quality control (QC) sample: Prestudy or in-study samples with a known (nominal) concentration that are treated as unknowns in the assay. During in-study runs, QC samples are used as the basis for run acceptance or rejection.

***Range* (ICH)**: The interval between the lower and upper concentrations of an analyte in samples for which it has been demonstrated that the analytical procedure has an acceptable level of accuracy and precision.

***Repeatability* (ICH)**: The precision of repeated measurement under the same operating conditions over a short interval of time (within one run), also termed intrabatch or intrarun precision.

***Reproducibility* (ICH)**: Precision of repeated measurements between analytical laboratories; also termed intralaboratory precision.

***Robustness* (ICH)**: A measure of the capacity of analytical methods to remain unaffected by small but deliberate variations of the experimental parameters; indicates the reliability of the method during routine use.

Run: A set of standard curve calibrators, validation samples or QC samples, or study samples that are analyzed in a single group of measurements; it is synonymous with batch.

***Selectivity* (ICH)**: Ability of a bioanalytical method to measure particular analyte(s) in a complex medium without the interference from other components of the mixture.

***Specificity* (ICH)**: The ability to unequivocally measure the analyte in the presence of other components including related compounds or matrix components.

Upper limit of quantitation (ULOQ): The highest concentration of an analyte in a test sample that can be determined quantitatively with suitable accuracy.

Validation: Demonstration that a method is suitable for the intended use; it is typically demonstrated by establishing validation parameters that are applied to sample analysis.

Validation samples: Biological matrix samples spiked with the analyte at predetermined concentrations; it is used during prestudy validation to assess accuracy and precision.

5.6.1 INTRODUCTION

Microarrays are grids of biomolecules (DNA, proteins, carbohydrates, small molecules) in which each element of the grid performs a specific assay such as identification of a specific binding molecule or measuring a particular enzymatic activity. A single sample is analyzed on each microarray providing simultaneous measurements for multiple parameters. Typically a complete experiment involves a large number of microarrays resulting in huge datasets. This deluge in data has led to approaches for integration of diverse datasets to enhance our understanding of both an individual molecular function and elaborate biological processes.

This potential of microarrays to facilitate global analysis of genes and gene products has led to its adoption in nearly every area of biological science—from basic research to clinical diagnostics. They are being used to tackle one of the major challenges in the postgenomic era—to understand the regulation, expression, and function of entire sets of genes, transcripts, and proteins. This information will help in characterizing complex biological processes at the molecular level in various cell types, both in normal and in disease states.

Since their conception in the mid-1990s, microarrays have seen widespread use in almost all aspects of biological research and their range of applications continues to expand. These include (1) biomarker discovery, to find genes that can be used for measuring and following disease progression; (2) target selectivity, to identify genes that can distinguish one disease from another as well as subclasses of disease; (3) pharmacology and toxicogenomics, to help in identification of poor compounds and to optimize the selection of promising leads; and (4) drug screening, identification of protein activity modulators. As the cost of microarrays continues to drop, it is clear that microarrays are becoming a more integral part of the drug discovery process. In short, microarrays are redefining the drug discovery and development process by providing greater knowledge at each step and by helping to understand the complex workings of biological systems.

This chapter provides a technical overview of microarrays, including information on array formats, production and use of microarrays for interrogating various molecular species—DNA, RNA, and proteins—and analysis of data. The challenges in experimental design to maximize microarray data quality, and the use of microarrays in understanding intracellular molecular networks as well as in drug discovery and development, are also discussed.

5.6.2 ARRAY FORMATS

5.6.2.1 Planar Arrays

High-Density Microarrays. High-density arrays are ideally suited for analyzing a small number of samples against thousands of genes, proteins, or small molecules. Early transcript profiling studies used high-density arrays in the context of target discovery with the objective of obtaining a short list of high-priority candidates that showed interesting expression patterns in disease states [1]. Arrays of oligonucleotides representing the entire human genome have been used for discovering polymorphic loci as well as the presence of thousands of alternative alleles [2, 3]. Other uses of high-density DNA arrays include determination of methylation patterns [4] and identification of transcription factor binding sequences [5].

Manufacture of high-density protein arrays presents a greater challenge due to the inherent heterogeneity in the physico-chemical properties and stability of proteins. However, arrays of recombinant proteins representing all yeast open reading frames (ORFs) have been manufactured and used for identification of novel binding activities [6]. *Escherichia coli* transformed with cDNA libraries to express mammalian proteins have been arrayed to identify autoantibodies in serum from the mouse model of systemic lupus erythematosus [7].

Low-density Microarrays. Low-density arrays can be used for simultaneously performing less complex analysis on many different samples [8]. The ability to rapidly screen thousands of biological samples for multiple parameters in the same assay makes the process cost-effective and easy to perform. This format is based on either using slides with hydrophobic barriers to create wells [9] or the 96-well microtiter plate formats, in which each well contains replicate mini-arrays of spots [10].

Low-density arrays are becoming increasingly popular for cytokine measurements due to the relative ease with which preexisting conventional enzyme-linked immunosorbent assay (ELISA) assays can be adapted to a miniaturized format [11]. In addition, low-density DNA arrays are being used for measuring polymorphisms to determine drug toxicity [12], and expression signatures obtained from high-density arrays are being used to guide the design of arrays with small sets of genes for use in cancer subclassification and prognosis [13].

Over the last few years, several different types of microarrays of various probe densities and content—DNA or protein—have become commercially available (Table 5.6-1). These provide microarray tools for analyzing samples derived not only from human tissues, but also from a wide spectrum of other species ranging from bacterial pathogens to Arabidopsis to mouse.

5.6.2.2 Solution Arrays

An alternative approach to planar arrays is three-dimensional arrays in solution. These have the advantage of parallel analysis and high throughput, in addition to better kinetics of binding in solution compared with planar arrays [14]. Positional information in these arrays is retained by a variety of methods such as fluorescence-encoded beads (two dyes with varying ratios incorporated into the bead set) and bar-coded nanoparticles (self-encoded with submicron metal stripes). The independence of each element offers the flexibility to multiplex either a few or thousands of measurements without the need to customize each assay. The high degree of reliability and reproducibility has resulted in the development of fluorescence-encoded beads for multiplex diagnostic assays [15].

This article will focus on technical issues, applications, and future directions in the use of planar arrays.

5.6.3 FACTORS FOR CONSIDERATION

5.6.3.1 Surfaces

Solid Supports. A wide variety of support materials have been used for manufacturing microarrays. Glass is the most commonly used support due to its

TABLE 5.6-1. A Partial List of Commercially Available Ready-to-Use Microarrays

Array Type	Company	URL	Brief Product Description
High-density oligonucleotide	Affymetrix	www.affymetrix.com	*In situ* synthesized oligonucleotides with multiple perfect match and mismatch probes per target gene.
High-density oligonucleotide	Agilent	www.agilent.com	60-mer probes in predesigned printed arrays; custom microarray design service is also available.
High-density oligonucleotide	Applied Biosytems	www.appliedbiosystems.com	60-mer probes designed to be within 1500 bases from the 3′ end of the transcript spotted on each chip.
Low density oligonucleotide	Mergen	www.mergen.com	60-mer probes printed in 16 replicate arrays per slide with 1000 probes in each array.
Low-density DNA	Superarray	www.superarray.com	Pathway-specific probes (up to 500 target genes) arrayed as 400-bp cDNA or 60-mer oligonucleotides.
Multiple content	Pamgene	www.pamgene.com	Printed oligonucleotides, peptides, or proteins as 4 or 96 replicate arrays on chips or plates, respectively.
Peptide	JPT Peptide Technologies	www.jpt.com	Printed peptide (12 to 15-mer) arrays for profiling of protease, kinase and phosphatase substrates.
Peptide	Pepscan systems	www.pepscan.nl	Arrays printed with 1200 protein kinase substrate peptides.
Protein	Invitrogen	www.invitrogen.com	Slides printed with recombinant proteins (yeast or human).
Antibody	Pierce	www.piercenet.com	Four to sixteen antibodies for ELISA assays printed in replicate arrays in 96-well format.
Antibody	BD Biosciences	www.clontech.com	Over 500 antibodies spotted for comparative profiling of protein levels from two samples.

low background fluorescence and amenability to automation [14]. Polystyrene with fluorescence and binding properties similar to glass is beginning to be increasingly adapted for microarray use [16]. These surfaces are usually modified by coating with one-, two-, or three-dimensional structures that provide either covalent attachment chemistry or enable binding of molecules through adsorption. Other microarray surfaces include membranes such as nitrocellulose and nylon and gold or silicon films [17–19]. Synthesis of oligonucleotides has been performed *in situ* on fused silica wafers [20], and peptide arrays have been synthesized on cellulose and polypropylene membranes [21].

Chemistry. Microarray surfaces must maintain the stability and activity of attached biomolecules, while remaining surface-bound through all processing steps. Spot morphology and background noise, either due to nonspecific sample binding or from the detection system used, are important issues to be considered in choosing the right immobilization chemistry. A variety of surfaces have been derivatized to expose various active groups; these determine the type of attachment—ionic or covalent—of the biomolecule to the surface [22].

Polylysine, which results in an amine surface carrying a positive charge, was among the early microarray surfaces used for binding to negatively charged biomolecules [23]. Membranes such as nitrocellulose and nylon that have traditionally been used for a variety of blotting applications have been modified for microarrays by application onto glass backing [17]. Table 5.6-2 provides commercial sources of commonly used surfaces for printing nucleic acids and proteins.

Oligonulceotides modified to carry an amino group or proteins through their lysine residues can be covalently attached to aldehyde- and epoxy-derivatized surfaces. Other reactive surfaces used to covalently link both DNA and proteins include N-hydroxy succinimide [20] and maleimide [24]. Proteins expressed with polyhistidine and biotin tags have been attached to surfaces coated with nickel chelate and streptavidin, respectively [25, 26]. This strategy is likely to result in the proper orientation of the displayed molecules on the surface, thereby improving their functionality and stability.

Heterobifunctional cross-linkers have been used to attach activated biomolecules on surfaces functionalized with either aminosilane [27] or mercaptopropylsilane [28]. These strategies have resulted in up to fourfold higher signal-to-noise ratios compared with the polylysine surface for arrayed antibodies [29]. Specific immobilization via interaction of surfaces functionalized with salicylhydroxamic acid derivatives and phenyldiboronic acid-labeled nucleic acids and proteins has also been demonstrated [30].

A new generation of chemistries has introduced poly(ethylene glycol)-functionalized surfaces that prevent nonspecific protein binding, thereby removing the need for a blocking step during processing [31]. This commercially available chemistry also offers a wide variety of additional functional groups. A large spacer between the support and the biomolecule results in higher analyte binding by avoiding steric hindrance [29]. Three-dimensional surfaces used for arraying biomolecules were shown to increase binding capacity and reduce denaturation of immobilized molecules, but they slowed down reaction kinetics due to reduction in diffusion rates [32]. These same chemistries are applied for biomolecule attachment to beads in the manufacture of suspension arrays.

5.6.3.2 Probes

Printing. Printing refers to spotting arrays of presynthesized biomolecules directly onto a solid surface. This versatile approach can be applied to generate microarrays of almost any biomolecule in conjunction with a proper im-mobilization method. Printing can generate many copies of the same array more efficiently than *in situ* synthesis because the immobilized molecules need to be synthesized only once. Several kinds of microarray printing technologies have been developed (Table 5.6-3), but the most commonly used method uses contact printing. In this method, pins are used to transfer samples from a source to the solid support by direct surface contact. Noncontact piezoelectric printers, which are also often used, can print more spots per unit time than contact printers by employing an electric current to accurately and rapidly dispense samples onto the solid support. Although the reproducibility of spot volumes delivered by contact printers typically has a

coefficient of variation (*cv*) below 20%, piezoelectric printers have greater control over the volume dispensed resulting in *cv*s of under 5%.

"Dropouts" or missing spots can be a problem, especially during high-throughput manufacture, and are primarily due to clogging of the dispensing components in the arrayer. To identify dropouts, microarrayers can be fitted with optical devices that can monitor dispensing and provide data on dropouts that can then be used to "fill in" missing spots. This system has vastly improved the quality of microarrays, reducing the need to print replicate spots of the same probe.

Other less-common deposition methods include electrospraying in a stable cone-jet mode to generate highly reproducible spots of as little as 50-pL volumes [33] and a laser transfer technique that allows the accurate deposition of picoliter volumes of proteins onto the solid surface [34].

In Situ Synthesis. Two typical *in situ* synthesis approaches are light-directed parallel synthesis and peptide synthesis on membrane (SPOT) synthesis. Although the former approach was initially developed for peptide synthesis [35], it has been adapted for the synthesis of DNA microarrays. This method uses a combination of photo-lithographic masks and combinatorial chemistry to synthesize oligonucleotides on fused silica wafers [36]. High-density arrays have also been manufactured by maskless methods using either digitally controlled aluminium mirrors to fabricate oligonucleotides by photodeposition [37] or by phos-phoramidite chemistry in microfluidic chips with three-dimensional nano-chambers [38].

The maskless method is also being used to create peptide arrays in microfluidic chips by parallel synthesis using digital photolithography and photogenerated acid during the deprotection step [39]. Peptide arrays have also been manufactured by SPOT synthesis using a combination of novel polymeric surfaces, linker and cleavage chemistries, as well as robotic liquid-handling systems [40]. These methods involve alternate synthesis and washing steps, increasing the possibility of contamination by reagents from adjacent spots, and thereby limiting array density [41].

5.6.3.3 Sample Processing

DNA Analysis. Detection of single nucleotide polymorphisms (SNPs) was one of the early applications of high-density oligonucleotide arrays [42, 43]. More recently these arrays have also been used to assess DNA copy numbers [44]. Each of these measurements requires the initial extraction of genomic DNA, which is then processed using several different methods each designed to incorporate labels for visualization of binding to specific probes on the array. Fragments from restriction digested genomic DNA were ligated with adaptors, amplified, and enzymatically end-labeled with biotin followed by hybridization to oligonucleotide arrays [42, 44]. Alternatively, labeling was done by incorporation of a biotin-tag during primer extension after hybridization of unlabeled amplified DNA fragments [43]. The biotin was then detected using Streptavidin conjugated to a fluorescent dye.

Genome-wide DNA–protein interactions have been mapped using intergenic oligonucleotide microarrays [45]. In this approach, called chromatin immunoprecipitation (ChIP), epitope-tagged proteins of interest are allowed to bind specific regions in genomic DNA and then cross-linked. The DNA-bound epitope-tagged proteins are immunoprecipitated using a tag-specific antibody. The DNA is then

delinked from the protein and, after fluorescent labeling, hybridized to arrays for identification of regions that bind to the protein of interest. A similar approach has been used for identification of methylation sites in genomic DNA. In this method, oligonucleotide primer adaptors are attached to restriction-digested DNA, followed by a secondary digestion with a methylation-sensitive enzyme, labeling with a fluorescent dye, and hybridization to arrays [46]. These methods are providing a wealth of information on the factors that regulate gene expression and helping to understand these processes at a global level.

Transcript Analysis. Microarrays permit the rapid analysis of complex gene expression changes in cells and tissues during development, both normal and disease. These changes give distinct patterns that can be used for discovering new disease-specific therapeutic targets, and molecular diagnostics, as well as for following treatment efficacy and disease prognosis.

Typically for transcript profiling, a labeled nucleotide is incorporated during reverse transcription of the total cellular mRNA pools. Not only does this approach require a large amount of RNA (50 to 200 μg of total RNA) for hybridization, but RNA purity is also a critical factor in array performance due to potential nonspecific binding by other labeled macromolecules [47]. Arrays have been widely used for obtaining relative mRNA concentrations between two samples, test and reference, in which each sample is labeled with a different dye (typically Cy3 and Cy5), followed by mixing of the samples before hybridization [48]. An alternative method avoids incorporation of bulky dyes during reverse transcription by incorporating amino allyl labels to which N-hydroxyl succinimidyl dyes are chemically coupled in a later step [49].

The use of a common reference RNA allows for the comparison of data between various array experiments. Typically a pool of RNA derived from a variety of tissues is used as a reference sample. Efforts are being made to implement common standards (MIAME, minimal information about a microarray experiment) for transcript profiling through the MGED Society to enable data sharing between different groups [50].

Methods in which the amount of mRNA has been amplified to produce labeled cRNA, by incorporating a T7 RNA polymerase promoter site into one end of the cDNA followed by *in vitro* transcription are also widely used [51]. In this method, quantitative estimates of the amount of each transcript in a given sample can be calculated. In single-sample labeling experiments, a reference RNA may be spiked in during sample labeling and hybridization to facilitate quality control of the process as well as for comparison of data between different arrays.

Despite its current widespread use and the drive toward ensuring high-quality microarray data by the implementation of MIAME guidelines, very little is known about the extent to which application of different technologies influences the outcome of transcriptional profiles and differential expression. However, microarray users should be aware of studies that have attempted to present a comprehensive evaluation encompassing different probe types (oligonucleotides and cDNAs), labeling techniques and hybridization protocols [52].

Protein Analysis. The early adaptation of protein microarrays is the reformatting of already available ELISAs. In these assays, which were first described by Roger

Ekins [53], a protein antigen is identified and its quantity is measured using two antigen-specific antibodies—one surface-immobilized to capture the antigen, and the other chemically labeled to bind the captured antigen in the solution phase. The second antibody produces a detectable signal through the label. This method, in which the protein sample does not have to be labeled, has been widely used for measuring cytokine levels in a variety of samples such as serum and tissue culture supernatants [54, 55]. Protein expression profiles have also been measured by capturing dye-labeled protein lysates derived from cells and tissues on arrays of antibodies. These measurements have largely been ratiometric in which two samples each labeled with a different dye using protocols similar to those used for transcript analysis are mixed and incubated with arrays of antibodies [56, 57]. Single-sample analyses could be performed by spiking known amounts of control proteins into the samples before labeling.

5.6.3.4 Signal Detection

Detection Chemistries. The most prevalent method for detecting binding of target to immobilized probes on microarrays are fluorescent dyes, of which Cy3 and Cy5 are the most widely used especially for differential transcript and protein profiling [58], whereas single-target hybridizations are commonly performed with fluorescein isothiocyanate [51]. Although Alexa dyes allow use of more than two colors in a single experiment, they are less commonly used [59]. Enzyme-labeled fluorescence (ELF), a phosphatase substrate that results in a precipitable product, has been used for both DNA and protein arrays [60].

Chemiluminescent detection is also used, mainly to detect antigen capture on antibody arrays by sequential incubations with biotinylated secondary antibodies and Streptavidin-conjugated horseradish peroxidase (HRP) [61]. Phosphorylation of arrayed kinase substrates in the presence of radiolabeled adenosine triphosphate (ATP) has been detected by autoradiography [62].

To increase sensitivity of detection, several signal amplification methods have been applied to the various types of molecular targets. Tyramide signal amplification (TSA) uses biotinyl-tyramide, an HRP substrate, to accumulate biotin at the reaction site. The “amplified” biotin is then detected using Streptavidin-HRP in conjunction with substrates that result in products detectable either by fluorescence, chemiluminescence, or colorimetry [63]. Other signal amplification methods include rolling circle amplification (RCA) in which an oligonucleotide-conjugated antibody binds to biotin on the target, followed by hybridization of a circular DNA molecule to the oligonucleotide. The circular DNA is then replicated using a DNA polymerase in the presence of a fluorescently labeled nucleotide [64]. Preformed branched DNA (dendrimers), each of which is attached to over 200 fluorescent dye molecules, have also been used for labeling array-bound targets [65].

Imaging Systems. Assay format and cost are the primary determinants of the kind of devices used for imaging arrays. Table 5.6-4 lists some commercially available imaging systems used for microarray normalization. Fluorescence-based scanners that use lasers to excite fluorescent dyes attached to the target molecule (for transcript profiling) or to a specific secondary detection reagent (for ELISA assays) are the most widely used for signal detection and imaging. These instruments

enable user-defined scanning resolutions and photomultiplier tube settings to adjust detection sensitivity. In addition, the availability of a wide range of fluorescent dyes makes this the most flexi-ble system for use in microarray image detection. Chemiluminescence-based detection systems using a charge-coupled device (CCD) together with conventional camera optics are also commonly used. Although the latter systems are flexible for applications in a wide range of assay formats, fluorescence scanners provide a higher range of sensitivity and dynamic range [66].

Label-independent methods such as surface plasmon resonance (SPR) can overcome variations caused by inconsistencies in labeling chemistries that are often seen in label-dependent detection systems. SPR has been used to measure affinities

in binding reactions, especially between antigens and their cognate antibodies. These highly sensitive systems are beginning to be adapted for microarray-based measurements [67]. Another recently described method relies on the change in fluorescence decay times of tryptophan and tyrosine residues in proteins to identify protein–protein interactions. In this method, a change in binding behavior of proteins in solution toward protein partners arrayed on a solid support is detected with regard to binding specificity and protein amount [68].

5.6.3.5 Data Analysis

Most commercial microarray imagers supply data extraction software that can accommodate the unique parameters of scanned images. In addition, printing precision has simplified the process of detecting spot boundaries and measurement of inter-spot distances. A useful consideration is the format for storage of primary scanned images (usually as tiff files) so as to be able to take advantage of future developments in image analysis software [69]. Storage of raw image files retains maximum information, allowing the use of different normalization, image extraction, and quality metrics.

Several commercially available software packages are available that interpret and transform an array image into a dataset (Table 5.6-5). Software programs grid the elements of the array as a first step in processing the image. Background-corrected intensity values for each spots are obtained using one of several options: local (area around individual spots) or global (average signal in area outside of the grid) background corrections, or user-defined values such as those from negative control data points contained within the array. After background-corrected intensity values have been calculated for each spot, the data are normalized with respect to sources of systematic and biological variation [70]. The choice of the normalization method is critical because it impacts precision of data comparison between arrays.

Several methods for statistical analysis of microarray data are available depending on the experimental setup and the kind of biological question that needs to be addressed. Initial approaches to analyzing microarray data focused on

unsupervised hierarchical clustering because these are simple ways in which data can be organized [71]. It is still the most commonly used analysis tool especially if the experiment has been designed to obtain a bird's eye view of transcript or protein profiles during a particular process. Machine learning techniques such as neural networks [72] and support vector machines [73] should be used for more advanced analyses when preliminary information can be used to guide data interpretation. Most software packages have a user-friendly graphical user interface (GUI) that enables performing a number of simple analysis, including data normalization, various kinds of clustering, and principal component analysis.

5.6.4 TYPES OF ARRAYS

5.6.4.1 DNA Arrays

Transcript Profiling. Transcript profiling was one of the earliest applications of microarray technology. In this application, fluorescently labeled cellular transcripts are hybridized either to arrays of spotted cDNA [19] or *in situ* synthesized oligonucleotides [36]. The former have generally been used for hybridization of a mixture of two transcript pools, each of which are derived from a different biological sample (such as diseased and normal tissue), and labeled with a different fluorescent dye (Cy3 and Cy5) before mixing [19]. A ratiometric analysis of fluorescence then helps to determine the relative expression levels of each transcript in the two samples. cDNA arrays have received wide acceptance within the academic community due to their low cost and ease of manufacture, as well as the ability to customize rapidly as new genomic sequence information becomes available. Customization of array content also easily accommodates the research interests of individual laboratories.

Oligonucleotide arrays, used for measuring transcript amounts from single samples, have the advantage of displaying a much larger number of very small spots (5 μ), enabling the interrogation of multiple probes for each transcript, including mismatch probes for determination of hybridization specificity [36, 74]. Currently, oligonucleotide arrays that display probes covering all predicted genes in the human genome are commercially available from several vendors (Table 5.6-1).

The ability to obtain global transcript profiles has accelerated the process of discovery in all areas of biology ranging from basic discovery to drug development and diagnostics. Correlations between gene-expression patterns and disease states have led to the selection of the best drug targets for pharmaceutical development as well as for monitoring therapeutic outcomes [75]. One area in which DNA arrays are making a critical impact is cancer, where expression profiles from hundreds of cancer tissue samples have allowed subclassification of cancers based on the identification of specific transcript expression signatures. These are likely to guide therapy and improve prognosis for cancer patients in the near future [76–79].

Physical Characterization of Genes. Oligonucleotide arrays have found use in the physical characterization of the genome by helping to map transcription factor binding sites and methylation sites [80]. These arrays, with their ability to package hundreds of thousands of spots on each chip, have been widely used for SNP discovery [81]. Clinically significant SNPs have then been rearrayed in a low-density

format for analyzing large numbers of samples to determine clinical validity. A U.S. Food and Drug Administration (FDA)-approved SNP genotyping array for CYP450 has recently been used to identify patients with a decreased ability to metabolize risperidone [10]. More recently, bacterial artificial chromosome (BAC) arrays have provided high-resolution maps of genetic changes, including gains and losses, as well as amplifications in chromosomal DNA by comparative genomic hybridization [82]. Other applications of oligonucleotide arrays have been to analyze splice variants by hybridization of labeled transcripts with arrays that combine exon and junction-derived probes, which are either specific or nonspecific to a splice event [83].

Cell Arrays. Immobilized arrays of plasmid DNA used to transfect cells in the presence of a transfection reagent are called cell arrays or reverse transfection arrays. These arrays are overlayed with cultured cells in medium and incubated so that cells superimposed on the DNA spot are transfected. The desired phenotypic change is visualized by staining the cells after a brief incubation period [84]. This format allows a variety of readouts, including cytoskeletal changes, apoptosis, and DNA replication, which can be either visualized with a laser scanner or a fluorescence microscope. Similar approaches have been used for increasing the throughput of loss-of-function studies using RNAi to monitor effects on cell phenotype [85, 86]. These studies enable functional whole genome screens without the need for expensive screening facilities.

5.6.4.2 Protein Arrays

Protein Profiling

Antibody Arrays. Antibodies are the most commonly arrayed protein class due to their structural similarity and stability. Many monoclonal antibodies generated over the years for binding to various epitopes on proteins offer a diverse source of capture and detection antibodies. These are being used in antibody arrays, especially for determination of growth factor and cytokine levels from a variety of biological samples [87]. Arrays have been multiplexed with antibodies that were developed and used for conventional ELISAs to measure levels of more than 50 cytokines with a high degree of sensitivity (pg/mL) from low sample volumes (less than 50 μL) [64]. However, each set of arrayed antibodies needs to be characterized for specificity of binding to the target molecule to ensure data quality. Recent studies have shown significant cross-reactivity of arrayed antibodies to proteins other than their intended targets [88].

Identification of disease biomarkers is a rapidly growing area of proteomic research. These biomarkers can enable better predictive capabilities in disease diagnosis and prognosis, as well as in drug development by identifying potential drug toxicities and side-effects. Although it has been suggested that antibody arrays can be used to profile serum and cell lysates, these measurements are complicated by the fact that protein concentrations in these samples cover 10 to 14 orders of magnitude [87], requiring systems that can simultaneously detect both low- and high-abundance proteins within a single array. The sample complexity issue may be alleviated by reduction in sample complexity before profiling. This can be accomplished using either liquid phase protein separation systems or by profiling

the protein complement of various cell organelles separately [89]. Samples can be labeled with either fluorescent tags followed by direct detection after capture or with other haptens such as biotin followed by detection with Streptavidin conjugated to a reporter molecule [90].

As well-characterized antibodies are available to only a small subset of total cellular proteins, profiling complex protein samples could be performed using arrays of *in vitro* synthesized antibody libraries [91]. This format has the advantage of being able to directly array bacterial cells rather than purified recombinant antibodies [92]. Once disease-relevant proteins have been identified through screening for global protein changes, arrays containing the "diagnostic" subset of antibodies that recognize disease-specific proteins can be used for high-throughput, large-sample analysis [66].

Antigen Arrays. Several studies have been performed to demonstrate disease identification by analysis of serum antibodies to clinically relevant proteins [93–96]. One study used arrays of autoantigen diagnostic markers to measure autoantibody titers in serum of patients with autoimmune disease [95]. In an extension of this study, autoimmune patient sera screened for binding to arrayed antigens identified specificity of autoantibody responses defining autoantigens relevant in human disease [97]. More recently, the diversity of B-cell response as a function of disease severity was measured using an array of over 225 distinct epitopes derived from several myelin-associated proteins. These arrays could identify distinct sets of epitopes and could demonstrate a correlation between reduced epitope spreading and improved disease outcome. This information is now being used to guide the development of a tolerizing DNA vaccine, which could potentially limit epitope spreading and improve disease outcome [98]. These antigen arrays have been shown to have a much higher sensitivity than conventional ELISAs with a three-log linear dynamic range [97].

Protein Function Arrays. The development of high-throughput expression and purification methods have made a large number of proteins available for arraying. A small amount of material (pg to ng) is sufficient for printing numerous arrays that can then be used to perform rapid, functional screens. The first genome-wide protein display, an array of all yeast ORFs, was used to screen for binders to calmodulin and phospholipids [6]. In this study, 5800 different yeast proteins with hexahistidine tags were arrayed on nickel-coated glass slides. The immobilized proteins were then probed with various labeled phospholipids resulting in the identification of more than 150 proteins that were shown to bind phospholipids for the first time. Other protein binding measurements include identification of protein–protein and protein–DNA interactions [99].

In addition to binding assays, functional properties are also being measured on arrays. Protein kinase activity has been determined either by immobilizing fluorogenic substrates followed by the addition of specific kinases [100] or on kinase arrays incubated with peptide substrates in the presence of radiolabeled ATP [101]. Protein kinase arrays have also been used for identification of inhibitors by incubating small-molecule binders in the presence of substrates demonstrating the ability of arrays to screen for kinase inhibitors [102].

G-protein-coupled receptors (GPCRs) currently make up the largest class of therapeutic drug targets and are an obvious choice for microarray-based drug

screening. An early study demonstrating the capability of microarrayed GPCRs for agonist and antagonist screening showed retention of activity through several activation/ deactivation cycles after ligand binding on arrayed rhodopsin [103]. Competitive binding assays in which mixtures of fluorescently labeled ligands and unlabeled inhibitors were used to demonstrate binding selectivity to different receptor subtypes have also been described [104].

Other Types of Protein Arrays. Peptides, arrayed either by deposition on the surface [105] or by *in situ* synthesis [106], have been used for epitope-mapping [107], measuring enzyme activity [108], and cell capture [105]. They have also been used for identification of peptide antagonists to proteins that are likely drug targets [109]. In addition, protease specificities were identified using peptidyl coumarin substrate arrays created by immobilizing the fluorescent coumarin leaving group via the C-terminus to the solid support, enabling synthesis of a high-diversity peptide library at the N-terminal end [110].

Arrays of peptide–major histocompatibility complex (MHC) complexes have been created on acrylamide gel-coated glass surfaces and used for ligand-specific capture of CD4(+) and CD8(+) lymphocytes. This approach should be useful to characterize multiple epitope-specific T-cell populations during immune responses associated with infection, cancer, autoimmunity, and vaccination [111].

Covalent mRNA–protein fusions were displayed on single-stranded DNA arrays through nucleic acid hybridization of the mRNA in the fusion molecule [112]. Similarly, capture agents such as nucleic acid aptamers have also been proposed for use in protein binding [113, 114].

5.6.4.3 Tissue Arrays

Tissue microarrays (TMAs) are displays of several tens to hundreds of tissue specimens on a single slide for parallel analysis [115]. Paraffin embedded tissue are generally used for arraying [116]; however, arrays have also been constructed from frozen tissue [117]. The ability to array archival paraffin embedded tissue opens up vast archives of patient samples for medical research. Arrayed tissue sections processed either for cytological staining or *in situ* hybridization, combined with automated image analysis systems, provides a powerful molecular profiling tool. TMAs are commonly used to confirm results obtained from expression microarrays, as well as in the development of diagnostic and prognostic markers for clinical applications.

5.6.4.4 Other Arrays

Although DNA and protein arrays continue to be widely used, other types of molecules are being arrayed and used for a variety of applications. These include small-molecule arrays in which individual members of a chemical library are deposited on a surface and used for performing binding assays with target proteins [102, 118, 119]. Several strategies are being applied for displaying small molecules on surfaces. The simplest strategy is to spot molecules on glass after mixing with glycerol to maintain “wetness’ after deposition. This strategy was used to create and screen arrays by spraying the target protein, human caspase 6, along with its fluorigenic substrate and screening for dark spots of enzyme inhibitors against noninhibitor fluorescent spots [120]. An elegant method that takes advantage of

DNA hybridization specificities to provide an address for arrays of protein nucleic acid (PNA)-tagged small molecules has been described [121]. More sophisticated libraries of molecules that selectively modulate activities of mutated kinases have been used to identify chemical inhibitors that switch off individual kinases [122].

Carbohydrate arrays have been developed and used as novel high-throughput analytical tools for monitoring carbohydrate–protein interactions such as profiling protein binding to various sugars and to measure enzymatic activity on sugar substrates [123]. These microarrays have also been used to discover anti-adhesion therapeutics by identifying carbohydrate binding specificities of pathogenic bacteria. The display of carbohydrate ligands on a surface in a manner that mimics interactions at the cell–cell interface is ideal for whole-cell applications [124]. Similarly, monosaccharide-based arrays of N-acetyl galactosamine and N-acetylneuraminic acid derivatives were used to identify binders to cholera and tetanus toxins [125].

5.6.5 IMPLICATIONS OF ARRAY TECHNOLOGY

5.6.5.1 Experimental Design

Microarrays are observed as tools for "descriptive" research and not for "hypothesis-driven" research, which is primarily driven to answer specific questions related to a known set of molecules. However, most microarray-based studies do have clear objectives and are designed to answer well-defined questions. The plan for specimen selection should follow from the objectives of the microarray study. Studies may either be exploratory, whose results should be confirmed, or designed to test various models; in which case, the experiments have to be designed in a focused manner [126].

Appropriate design of microarray studies is critical to draw valid and useful conclusions from the large amount of data that are invariably obtained from each experiment. Criteria for design will vary depending on the type of array used—DNA, protein, and small molecule—as well as the experimental objectives, and sources of variability within the system. Issues such as selection of samples, number of replicates needed, allocation of samples to dyes for ratiometric profiling, and sample size are important considerations in these studies [127].

Three sources of variation should be considered in the design of a microarray experiment: (1) biological, at the level of setting up of the cells, cell lines or animals, and sample treatment; (2) technical, which is introduced during sample processing; and (3) analytical, which highlights signal bias and readout [128]. To minimize each of these variations, the experiment should be set up such that the biological material to be used for analysis should be handled separately from the initiation of the experiment providing biological replicates. If this results in an unwieldy experimental setup, pooling the samples at some stage of processing may still allow a reduction in biological variance. This approach is risky in the event of the presence of an extreme outlier in the pool, because this can unduly influence the expression values obtained from the pool. Samples from every stage of the experiment with a likelihood of introduction of variation should be treated separately. Replicate measurements from the same biological sample helps to reduce technical variation.

TABLE 5.6-6. Experimental Design for Two Color Microarray-Based Comparisons of Transcript Profiles Between Disease and Healthy Tissue Samples

Design	Array 1		Array 2		Array 3	
	Dye 1 (e.g., Cy3)	Dye 2 (e.g., Cy5)	Dye 1	Dye 2	Dye 1	Dye 2
Reference	Disease Sample 1	Healthy sample	Disease Sample 2	Healthy sample	Disease Sample 3	Healthy sample
Loop	Disease Sample 1	Healthy Sample 1	Healthy Sample 1	Disease Sample 2	Disease Sample 2	Healthy Sample 2
Balanced Block	Disease Sample 1	Healthy Sample 1	Healthy Sample 2	Disease Sample 2		

Ratiometric analysis of signal by comparing signal intensities between two samples from the same spot reduces errors due to printing differences. This has led to the use of a reference sample in transcript profiling experiments, and it is an integral part of differential profiling, making the choice of the reference sample critical. The most important considerations in choosing the appropriate standard are that it is readily available, homogeneous, and stable over a period of time. The reference sample does not need to have any biological relevance, because it merely serves to compare expression profiles between different experiments performed in different laboratories. Among the standards that have been used are mRNA populations obtained from a wide variety of cells or tissues with the aim of lighting up every element on the array. Alternatively, a reference sample is prepared from the samples that will be assayed in the experiment to ensure that every transcript present in the test samples will be represented in the reference standard [126]. Care has to be taken, however, that no transcript in the reference sample saturates the signal in the detection system.

If a direct comparison needs to be made between two samples, for example, samples from pooled healthy tissue with samples from disease tissue, it would be necessary to perform forward and reverse labeling to remove any dye bias that may alter the results [129]. Swapping dyes between samples reduces systematic bias in the data that can be corrected during the normalization step [130]. Alternative design strategies that have been suggested are the balanced block design [131] and the loop design [132]. The same considerations can be applied to two-color antibody array-based protein profiling [133]. These experimental design strategies have been briefly illustrated in Table 5.6-6.

5.6.5.2 Molecular Network Analysis

Computational analysis is essential to transform the large amount of data generated by microarrays into a mechanistic understanding of various modules connecting at hubs and nodes to form molecular networks. Methods that identify the regulatory mechanisms underlying these modules and processes by an integrative analyses in the context of other data sources are often capable of extracting deeper biological insight from the data. Such integrative computational approaches include meta-analysis, functional enrichment analysis, interactome analysis, transcriptional

network analysis, and integrative model system analysis. In addition, comparative analysis, combining human data with model organisms, can lead to more robust findings [134, 135].

Such methods that analyze biological processes in terms of higher level modules can identify robust signatures of disease mechanisms. Application of these methods to understand human cancers have delineated molecular subtypes of cancer associated with disease progression and treatment response [76–78, 136, 137].

A closely integrated data warehouse has been constructed to link different kinds and numbers of biological networks to experimental results such as those coming from microarrays. The basic idea is to consider and store biological networks as graphs in which the nodes represent promoters, proteins, genes, and transcripts, and the edges specify the relationship between the various nodes. Direct links to underlying sequences (exons, introns, promoters, amino acid sequences) in a systematic way enable close interoperability to sequence analysis methods. This approach allows us to store, query, and update a wide variety of biological information in a way that is semantically compact without requiring changes at the database schema level when new kinds of biological information are added. Such a system can be set up using software available from the public domain [138].

5.6.5.3 Drug Discovery and Development

Target Discovery. Microarrays are increasingly being used in drug discovery for a wide range of applications, including target discovery and selection, pharmacology, and toxicogenomics [139]. The objective of using transcript profiling in target discovery is to identify a shortlist of candidate genes with distinct expression patterns during disease. Typical selection criteria include disease-specific changes in expression levels and tissue or cell-type selectivity [140]. A secondary screen is then typically used to examine the role(s) of short-listed genes by analyzing additional samples, and identifying correlations with disease progression. Validation experiments are performed to follow up the candidate genes using animal disease models or mice in which the target gene has been knocked out.

Network analysis is especially relevant to antimicrobial drug discovery. The relatively small size of microbial genomes enables data from profiling experiments to be used for modeling gene networks because these would be several orders of magnitude lower in complexity compared with human cellular networks. In addition, the availability of whole-genome nucleotide sequence data from a growing list of microbial genomes allows designing of probes for DNA arrays. Such microarrays are already being used to obtain a global perspective of host–pathogen interactions. This is beginning to make an impact on our understanding of pathogenesis and the strategies taken to combat infectious diseases, including the identification of novel drug targets [141].

Target Validation. Several approaches, including those that involve the use of arrays, can be taken to validate short-listed therapeutic candidates. Genes whose transcript profiles suggest additional analysis can be profiled using TMAs in tens to hundreds of tissues by immunohistochemistry [142]. TMAs can be used to identify heterogeneities between primary tumors and their metastases, as demonstrated in the analyses of erbB2 in primary and metastatic breast cancers

[143]. The expression of a target gene in normal tissue from various vital organs can also be assessed using TMA panels. It is well known that mRNA levels do not reflect protein quantities and function, so proteomic analysis may help in making better decisions on targets to be developed for therapeutics [144].

Cell-based gene knockouts can closely mimic the actions of potential drugs to identify phenotypic changes and potential side effects. The successful adaptation of RNA interference in a microarray format to facilitate efficient suppression of gene expression has enabled high-throughput target validation for a wide variety of cell types [85, 86].

Pharmacology. A study that monitored the expression patterns of the entire complement of yeast genes under a variety of experimental conditions and genetic backgrounds was used to categorize drugs into various classes based on the expression pattern changes they induced. This database is being used to stratify novel drugs based on their mechanism of action by monitoring the changes in expression induced by them [1].

Drug safety in animals is tested by monitoring a diverse spectrum of events, most commonly liver and kidney toxicity, and fatty liver. Transcriptional activation of drug metabolizing enzymes in livers of drug-treated animals or primary human hepatocytes has been widely used to identify drug metabolizing pathways. This helps to identify drugs early in development that might have toxicity issues due to inadequate metabolism [145–147]. In human populations, certain polymorphisms in the cytochrome P450 genes result in slow drug metabolism leading to toxicity. Additionally, the identification of SNPs in the cytochrome P450 genes of patients during clinical trials can help to stratify patients in whom the treatment is likely to be effective [148].

5.7.1 INTRODUCTION

Over the past decade, major research efforts have resulted in a wealth of sequence information for many genomes. In addition to the human genome, several other mammalian genomes have also been completely sequenced, providing a tremendous resource for biomedical researchers to examine gene sequences, their

Handbook of Pharmaceutical Biotechnology, Edited by Shayne Cox Gad.

regulation, and their role in health and disease. However, although we commonly talk about "the genome" when we refer to the genome sequence, every individual of a species has a slightly different genome sequence. It is this variation in the genome sequence that accounts for phenotypic differences, and for different susceptibilities to a large number of diseases. In humans, if we knew which sequence differences predisposed individuals to common human disorders such as hypertension or Alzheimer's disease, we could develop preventive treatments that could prevent disease, despite the genetic risk. It is this vision that has driven researchers involved in the Human Genome Project over the past years. Likewise, if we understood the genetic variation in model organisms, such as rats or mice, responsible for disease susceptibility or variability in drug metabolism and efficacy, we could use this information to test novel drugs more efficiently and target specialized drugs toward individuals with specific genetic predispositions.

Although there has been significant progress in biomedical research to suggest that this vision may one day become reality, we do not yet have a good understanding of the genetic differences in the genome sequence, and how they influence the development of disease. One reason why progress has been slow is the fact that there are so many differences. The sequence of any two human genomes differs in at least three million bases. Most differences in mammalian genomes are single base pair differences in the DNA sequence, but others include length variation in repeated sequences and chromosomal rearrangements. This presents a tremendous challenge to geneticists and biomedical researchers: How do you distinguish between DNA sequence variation that has no functional consequences and the differences that affect gene function and possibly the well-being of the organism? After all, only about 5% of any mammalian genome encodes for genes, and only small portions of the remaining 95%, have discernible functions. As a consequence, it is likely that most DNA sequence variation has no effect on the organism because it is located in these regions without (known) function.

To further identify the determinants of genetic disorders, different approaches have been used to zoom in on regions of the genome that contain the mutation(s) that are responsible for the genetic defect. Both commonly used approaches, family-based linkage studies and association analyses, require genetic markers, i.e., sequences that are variable between individuals and can be used to distinguish the DNA from different individuals. Even before the completion of the various genome sequencing projects, linkage analyses identified numerous loci in the genomes of both humans and model organisms that harbor genes involved in the development of a variety of common disorders. These studies used genetic polymorphisms, i.e., differences in the DNA sequence, to distinguish individuals with and without the disease and to identify regions shared by affected individuals. It is this initial use of DNA sequence variation as markers for genetic studies that this chapter will focus on. We will describe two types of genetic variation commonly used as markers in genetic studies, describe how they were discovered and can be interrogated by genotyping in large numbers of individuals, and will end by briefly describing the approaches of linkage and association studies that are aided by and rely on these genetic markers. Numerous review articles have summarized different aspects of this chapter, and we will focus primarily on the methodologies underlying the different genotyping approaches commonly used today in genetic laboratories.

5.7.2 SIMPLE SEQUENCE LENGTH POLYMORPHISMS (SSLPs)

5.7.2.1 General Description

Eukaryotic genomes contain interspersed repetitive sequence elements, many of which have no known function. Incredibly, these "nonfunctional" sequences comprise about 20% of the human genome [1]. It is thought that these repetitive motifs were generated by transposons or retrotransposons that replicate and then "jump" to other locations to propagate their genome, in the form of either DNA (in the case of transposons) or RNA (in the case of retrotransposons). Some repetitive sequence elements are long, about 1000–5000 base pairs (bp) in length, and they are known as LINES (long interspersed elements), whereas others are shorter, about 200–500 bp, and are known as SINES (short interspersed elements). The Alu element, approximately 300 bp in length, is the most abundant SINE in the human genome [2] and comprises about 3% of the human genome.

Another type of repetitive element consists of very short sequences (2 to 5 bp), arrayed in tandem. These sequences, called microsatellites, simple sequence length polymorphisms (SSLPs), simple sequence repeats (SSRs), or short tandem repeat polymorphisms (STRPs), tend to vary in unit size (from 5 to 30 units). The number of these tandem elements varies, and as a result, so does their length, making these sequences *polymorphic* (having different forms). The most abundant class of microsatellite repeat, is the dinucleotide repeat of cytosine and adenine, or (CA) · (GT) repeats [3, 4]. In the human genome, these dinucleotide repeat microsatellites occur every 30 to 60 kbp, corresponding to approximately 50,000 to 100,000 microsatellites in the 3 billion base pair human genome [5]. Other common microsatellites include trinucleotide and tetranucleotide repeats (3 and 4 bp repeats, respectively) [6].

The length of the microsatellite repeat is thought to be due to errors in DNA replication [7]. During DNA replication, the polymerase machinery is thought to "slip," either eliminating or adding repeat units. The deletion or addition of a single repeat unit occurs most frequently (91%) [8]. The frequency of this type of mutation, on average, is 1.2×10^{-3} per microsatellite, translating to roughly 1 in 1000 meioses (as determined by examining how often a parent passes an expanded or contracted microsatellite repeat to his/her offspring) [8]. The range of mutation frequency for any given microsatellite is 0 to 8×10^{-3} and seems to occur more frequently in the male vs. the female germline.

With a few exceptions, microsatellites do not have functional consequences on clinical outcomes. They are most commonly found in intergenic or intronic portions of a eukaryotic genome. However, it is important to keep in mind that, although the microsatellite is repeated throughout the genome, there is a unique sequence flanking it, corresponding to the location within the genome in which it integrated. Therefore, this class of polymorphic repeat is ideal for an assay that can tag a specific genome location for use in genetic studies, which will be discussed in detail in this chapter.

5.7.2.2 Discovery

The microsatellite was first discovered in 1981 by Miesfeld et al. [9] by screening a human gene clone library with a mouse 6-kbp (6 kilobase pair) ribosomal gene

nontranscribed spacer probe (rDNA NTS). They found this sequence was interspersed not only throughout the human and mouse genomes, but also in every other eukaryotic organism they studied—pigeon, frog, slime mold, and yeast. However, it was not identified in *Escherichia coli*. Therefore, the rDNA NTS has been conserved throughout all eukaryotes, but not down to prokaryotes. Miesfeld et al. then narrowed down the conserved element, which they called ECl (evolutionarily conserved), to a 251-bp fragment of the rDNA NTS that contained a tandem array of the (TG) · (CA) dinucleotide. However, the reason for its dramatic evolutionary conservation remained a mystery.

In 1989, two back-to-back manuscripts were published, by Weber and May [4] and Litt and Luty [3], reporting the use of microsatellites as genetic markers; i.e., they could be used to identify inheritance patterns from parent to offspring. By cloning and sequencing several microsatellites, it was found that each tandem repeat was flanked by a unique genomic sequence, thereby providing the ability to identify an individual's "genotype" at a specific DNA location (locus) containing a microsatellite. By sequencing 59 of these microsatellites, Weber and May found that more than half of them contained repeats of 13 or greater dinucleotides, with the longest being 30 units in length [4]. They went on to test 10 microsatellites for Mendelian inheritance. All microsatellites tested displayed expected Mendelian inheritance in three-generation families.

Figure 5.7-1 displays a cartoon example of the inheritance of a single SSLP marker. Each band represents the length of the microsatellite fragment, separated according to its length by gel electrophoresis. Each parent, being diploid, has two alleles for the microsatellite, each having a different number of dinucleotide repeats. The mother and father each contribute one of these alleles to their offspring, with a 50% probability of a child inheriting either allele. The inheritance of each allele from their parents is shown in the children, in the expected Mendelian ratios.

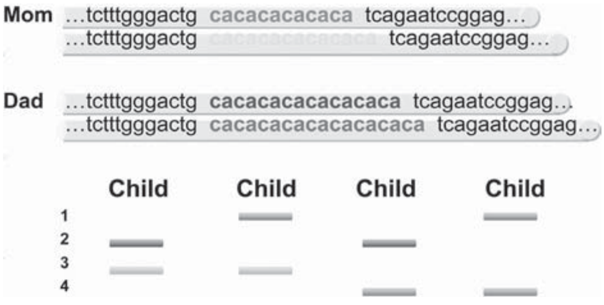

Figure 5.7-1. Schematic of SSLP genotypes. The top two bars represent a mother's chromosomal fragments containing two different alleles of a $(CA)_n$ repeat, the first having six tandem repeats (red allele) and the second having seven tandem repeats (green allele). The bottom two bars represent a father's alleles (eight repeats = blue; nine repeats = purple) for the same SSLP. The bottom represents genotypes from four children of the above parents, as they might appear on an electrophoretic gel. The four columns indicate four different children's genotypes for the SSLP, with the numbers indicating the four possible alleles. The colored bars correspond to the alleles inherited from the parents, representing all possible allele combinations according to Mendelian inheritance. (This figure is available in full color at ftp://ftp.wiley.com/public/sci_ tech_med/pharmaceutical_biotech/.)

The discovery of the microsatellite as a highly polymorphic genetic marker, and its ability to generate genotypes in a high-throughput manner, revolutionized genetic analyses of disease and greatly facilitated the mapping and sequencing of not only the human genome but also several model organisms, as discussed in the following sections.

5.7.2.3 Methods for Genotyping

The major advantage of genotyping using SSLPs over previously used genetic markers, e.g., restriction fragment length polymorphisms (RFLPs), is twofold. First, SSLPs are highly polymorphic, with alleles ranging anywhere from just a few to over 30 nucleotide repeat units. This greatly increases the likelihood that an individual will have alleles of differing sizes for any assayed SSLP, i.e., the marker is informative, and can be used across multiple families for genetic analyses [10]. In fact, many tens of thousands of SSLP assays have been developed for organisms ranging from human to mouse, rat, dog, cat, cow, chicken, pig, fish, frog, fruit fly, corn, rice, poplar, and yeast.
